Abstract

The willingness of a customer to pay for a product or service is mathematically captured by a price elasticity model. The model relates the responsiveness of customers to a change in the quoted price. In addition to overall price sensitivity, adverse selection could be observed whereby certain customer segments react differently towards price changes. In this paper the problem of determining optimal prices to quote prospective customers in credit retail is addressed such that the interest income to the lender will be maximised while taking price sensitivity and adverse selection into account. For this purpose a response model is suggested that overcomes non-concavity and unrealistic asymptotic behaviour which allows for a linearisation approach of the non-linear price optimisation problem. A two-stage linear stochastic programming formulation is suggested for the optimisation of prices while taking uncertainty in future price sensitivity into account. Empirical results are based on real data from a financial institution.

1 Introduction

In recent years there has been a significant shift by some industries to move away from cost based pricing, where the price of a product or service is based on the cost plus some fixed profit margin, to a more flexible demand-based pricing strategy, see Skugge (2011). Demand-based pricing is done by taking into account the willingness of a customer to pay for a product or service, i.e. price elasticity. The responsiveness of the quantity demanded of a product or service to a change in its price is a measure of elasticity and it is commonly referred to as a price response function. Examples of typical price response functions are the linear, the constant-elasticity and the s-shaped price response function, see Phillips (2005).

Knowing more about the customer would likely improve the predictive power of a response function. Cross and Dixit (2005) state that the key to customer-centric pricing is to set prices that accurately reflect the perceived value of products per customer segment, where a customer segment is a grouping of customers having similar characteristics and product preferences. In Agrawal and Ferguson (2007) bid-response models are presented for customised business-to-business bid pricing and they show that by making use of customer segmentation an increase in profits can be expected. In Phillips (2012) a pricing approach is suggested where price levels are determined per customer segment while taking price sensitivity into account.

In retail banking, specifically consumer credit, the pricing approach followed for many years was limited to risk-based pricing, see Edelberg (2006). The dependence on risk-based pricing could be attributed to the uncertainty in the expected revenue and costs associated with consumer credit. In Caufield (2012), however, it is argued that risk-based pricing is the lending industry’s version of cost-based pricing and that an increase in profit of between 10-25 percent could be expected with

*Corresponding author
a profit-based pricing approach. Such an approach would typically combine risk-based pricing and demand-based pricing in an attempt to maximise profits.

The problem being addressed in this study is the pricing of consumer credit products in retail banking. In addition to general price sensitivity, adverse selection is an important characteristic in retail credit that is likely to have a significant impact on pricing, see Stiglitz and Weiss (1981). The phenomenon in retail credit where low risk customers are more sensitive to an increase in prices compared to high risk customers can be attributed to adverse selection. Therefore, according to Thomas (2009), adverse selection needs to be taken into account as part of risk-based pricing since it influences the interaction between the quality of the customers and the probability of them taking up credit products. In Huang and Thomas (2009) a quantification for adverse selection is given within the context of risk pricing and they show how errors in the risk scoring models could effect profitability.

The literature contains empirical evidence of the existence of price elasticity and adverse selection in retail credit. Specifically, in Park (1997) results indicate that for the credit card industry a decrease in demand is associated with an increase in price. This is also the case for the credit industries in less developed economies, see Karlan and Zinman (2008). The study by Ausubel (1999) also showed clear evidence of adverse selection within the credit card industry and in Phillips and Raffard (2009) evidence is provided of adverse selection in the US sub-prime auto lender market. In Einav et al. (2012) an empirical model of demand for subprime credit is developed that takes adverse selection into account. Applying their model on detailed cost data they find that optimal prices dictate lowering down payment requirements for low risk customers and increasing it for high risk customers.

Most of the literature on the topic of pricing, as outlined above, focusses on determining the factors that influence price setting and the relationships that may exist between consumer behaviour and pricing. Only recently have there been efforts to formalise the retail credit price optimisation problem and the challenges faced with obtaining optimal solutions. In Phillips (2013) the pricing problem for credit consumers entails determining optimal prices per pricing segment according to an objective function that combines the net interest income with price sensitivity. The log-concavity property of the said objective function allows for the efficient generation of optimal prices provided that any additional side constraints preserve convexity of the feasible region. No numerical results are presented in that paper. In the paper by Oliver and Oliver (2012) a numerical algorithm is provided to find optimal prices to maximise return on equity by considering price response and default risk. Their approach is based on the solution of non-linear differential equations.

The price optimisation model considered in this paper is based on the work by Phillips (2013) and takes uncertainty in future price sensitivity into account. To the best of our knowledge uncertainty in future price sensitivity has not been considered previously in any study concerned with retail credit price optimisation. Furthermore, a response model is suggested that overcomes non-concavity and unrealistic asymptotic behaviour. This allows for a linearisation of the retail price optimisation problem making it more tractable for a stochastic linear programming approach, see Higle (2005). The empirical results presented in this paper are based on real data from the South African retail bank Absa, a subsidiary of Barclays Bank Plc.

In the next section empirical evidence is provided that support the use of a stochastic programming framework. In Section 3 the income function used to approximate the net present interest income with is introduced and details are provided of the newly proposed response function. A linear approximation of the newly proposed response function is provided and incorporated into a linear programming model for solving the credit price optimisation problem with multiple customer segments. In Section 4 the basic problem is extended to cater for uncertainty in future price sensitivity by formulating the credit price optimisation problem as a linear stochastic programming problem. Empirical results are provided in Section 5 that highlights the benefits of following a stochastic programming approach based on real data. Finally, summary remarks and a conclusion
are provided in Section 6.

2 Price sensitivity and adverse selection

The optimisation problem addressed in this paper is solving the retail credit price optimisation problem by taking uncertainty in future price sensitivity into account. That is, the output from solving this problem are the optimal prices that will be quoted to prospective customers, i.e the loan interest rates, such that the interest income to the lender, discounted with the effect of price elasticity and adverse selection, will be maximised. In this section evidence of the existence of price elasticity and adverse selection will be provided and a case will be made for using a stochastic programming framework for solving retail credit price optimisation problem.

To illustrate the effect of price sensitivity and the effect of adverse selection, empirical tests were performed using data obtained from a financial institution in South Africa over a period of three years. The variables contained within the data set included:

- whether a customer took up a loan \((Y = 1)\) or not \((Y = 0)\)
- the quoted interest rate \((r)\)
- the repurchase rate \((r_0)\)
- the loan amount \((a)\)
- the loan term \((n)\)
- the probability of default \((p)\)
- the loan application date.

The probability of a customer taking up a loan is expressed as the following response function obtained from fitting a logistic regression model:

\[
R(r,a,n,p) = \frac{1}{1 + e^{-(\beta_0 + \beta_1 r + \beta_2 a + \beta_3 n + \beta_4 p + \beta_5 r_0)}}
\]

with \(\beta_1\) to \(\beta_5\) the regression coefficients that are estimated through the maximum likelihood method. Note that for ease of illustration interaction terms between the different variables have been omitted. Furthermore, instead of following the customary approach of modelling the margin \(r - r_0\), the repurchase rate \(r_0\) is considered separately and is shown in the results to feature in some of the interaction terms. The response function \(R(r,a,n,p)\) gives the probability that a customer with a probability of default of \(p\) will take up a loan of size \(a\), term of \(n\) and with a quoted price of \(r\), provided that the current repurchase rate is \(r_0\). In subsequent sections the notation \(R(r,a,n,p)\) will be used to obtain a two dimensional response function in terms of the variable \(r\) by supplying constant values for \(a, n\) and \(p\) to the logistic regression model (1).

A stepwise logistic regression was performed (p-value of 5%) and a c-statistic of 0.608 was obtained. Although a perfect model would have yielded a c-statistic of one it should be noted that the data set under consideration is limited in the number of variables and with additional variables capturing information such as demographics, application turn-around time, macro economic factors, etc. an improved c-statistic would most likely be possible.

Figure 1 shows the response graph of price vs take-up generated from the response function \(R(r,a,n,p)\) by substituting averages from the data set for \(a, n\) and \(p\). The graph clearly shows that price elasticity exists since lower take-up rates are associated with an increase in price. Adverse selection is a term used to refer to a market process where "bad" results occur when buyers and sellers have asymmetric information: the "bad" products or customers are more likely to be selected.
The resulting effect in credit retail is that low risk customers are more sensitive to an increase in prices compared to high risk customers. To illustrate the effect of adverse selection different levels of probability of default ($p$) were substituted into the response function $R(r, a, n, p)$ for low risk and high risk customers respectively. Figure 2 shows that the take-up for high risk customers was higher compared to low risk customers for the same quoted price, implying that adverse selection does indeed exist for this data set.

Another aspect to consider are the economic conditions over time. In Figure 3 a graph is provided of how the repurchase rate in South Africa has changed over time. It is anticipated that with changing economic conditions there might be a change in sensitivity towards credit prices. In order to test this hypothesis in a very pragmatic way two points in time have been identified that partitions the data set into three periods. The first period coincides with the the first five months during which the repurchase rate dropped significantly, as can be seen from Figure 3. The next period coincides with the subsequent 18 months during which a moderate rate of decrease in repurchase rate can be observed. For the last 13 months the repurchase rate remained unchanged.

The logistic regression model (1) was fitted using the data partitions for each of the three time periods. For the first time period a c-statistic of 0.621 was obtained, for the second time period a
c-statistic of 0.618 was obtained and for the last time period a c-statistic of 0.6 was obtained.

Figure 4 provides a graph for each of the response functions fitted to each of the time periods. The lack of sensitivity towards price increases in the first period could be attributed to an optimistic economic outlook due to the steep decline in repurchase rate within a short period of time. Irrespective of the reason for this phenomenon, it is clear that economic conditions could have an effect on price elasticity. Empirical evidence (not reported here) also suggest this to be true for adverse selection. It is, therefore, a reasonable approach to take potential future price sensitivity into account when determining prices to be quoted to prospective customers. For instance, if we have to determine prices at this point in time we could consider the three response graphs depicted in Figure 4 as potential future scenarios with respect to price sensitivity. That is, in the near future the current repurchase rate level may either drop significantly, or only moderately or remain unchanged as was historically the case. Note that the proposed optimisation approach below will allow us to also incorporate potential future scenarios that are not captured as part of the historic data. For instance, another potential future scenario to consider might be that the current repurchase rate will increase in the future, especially if it is currently at a low level.
In view of the above, the optimization question at hand is, therefore, to determine optimal price levels by considering the uncertainty in future price elasticity which could be represented by a finite set of potential future scenarios. Preceding the details of the proposed model that addresses this problem, the fundamental building blocks of the credit price optimisation problem is set out below.

3 A concave linear approximation of the objective function

Let the probability of default for a customer be denoted by \( p \) and the loss given default by \( \delta \). Furthermore, let \( a \) be the loan amount, \( n \) the term (in months) and \( r \) the price (annual interest rate).

By denoting \( r_0 \) as the annual repurchase rate, i.e. the cost of funding the loan, an approximation of the net present interest income is given by the following, see Phillips (2013):

\[
I(r, a, n, p) = na(r/12 - r_0/12) - ap\delta
\]  

(2)

The profitability of the customer is expressed in terms of the approximated income \( na(r/12 - r_0/12) \) minus the cost of risk \( ap\delta \). The attractiveness of the approximation \( I(r, a, n, p) \) is that the function is firstly, linear in the rate \( r \) and secondly, instead of relying on a sequence of probability of defaults over time, it is written in terms of an overall probability of default \( p \), see Phillips (2013) for a detailed discussion. For the remainder of this paper we assume that \( \delta = 1 \).

The approximate net present income function (2) can now be generalised to accommodate a customer segmentation approach. In practice prices are determined per customer segment in order to differentiate prices according to product and customer characteristics. For instance, an obvious segmentation scheme for credit is to let customers with similar credit scores and that apply for loans having similar terms and loan amounts be in the same segment. Let \( \delta \) be the loan amount, \( n \) the term for a customer segment \( c \) and \( r \) the price (annual interest rate).

\[
\tilde{I}(r_c, a_c, n_c, p_c, v_c) = v_c a_c n_c (r_c/12 - r_0/12) - v_c a_c p_c \delta
\]  

(3)

with \( v_c \) the number of loan applications (volume) for customer segment \( c \in C \). The assumptions underlying (3) is that a 100% take-up is expected by all the customers in the segment for the quoted price \( r_c \). In order to reflect the fact that income is conditional on customer take-up and to adjust the income function accordingly, we turn our attention to price elasticity.

In contrast to Phillips (2013), we do not suggest fitting the model (1) for each customer segment \( c \in C \). The motivation is that data availability in some of the customer segments may lead to response functions with poor predictive power. The alternative is to obtain a single response function \( R(r, a, n, p) \) that is fitted by taking the segment averages, \( a_c, n_c \) and \( p_c \), for each customer segment \( c \in C \) as input. That is, the resulting data set will have \( |C| \) number of cases. It is anticipated that the average take-up for a customer segment \( c \in C \) given by \( R(r_c, a_c, n_c, p_c) \) will have a better smoothing effect over segments with limited cases. Considering the income function (3) and the response function (1), the resulting credit price optimisation problem that maximises the approximate net interest income per customer segment is defined as:

\[
\max_{v_c \geq 0} \sum_{c \in C} I(r_c, a_c, n_c, p_c, v_c) R(r_c, a_c, n_c, p_c)
\]  

(4)

The optimisation problem (4) is an unconstrained problem and solving it using standard non-linear optimisation methods will produce a unique solution since the term \( I(r, a, n, p) \) is linear and \( R(r, a, n, p) \) is an increasing failure rate distribution (see Phillips (2012)). Incorporating constraints into the problem would still result in optimal solutions provided that the feasible region remains
Figure 5: The effect of fitting the piece-wise response function $\tilde{R}(r, a, n, p)$

a convex set, see Boyd and Vandenberghe (2004). In a practical setup one of the most useful constraints to consider in credit price optimisation is the volume constraint

$$v_c R(r_c, a_c, n_c, p_c) \leq V$$

with $V$ an upper limit on the proportion of customers defined by the segment $c \in C$. This could be used to limit the volume of customers having a specific risk profile. It should be noted, however, that by adding a constraint of the form (5) to the optimisation problem (4) the feasible region would be a non-convex set since the function $R(r, a, n, p)$ is defined to be neither convex nor concave. Apart from this the response function $R(r, a, n, p)$ also has an unrealistic infinite support with respect the the price variable $r$. In an attempt to address both these issues the following response function is suggested:

$$\tilde{R}(r, a, n, p) = \begin{cases} 1/(1 + e^{-\phi(r)+\alpha}) & \text{if } \phi(r) \geq \alpha \\ 0.5 + 0.25\phi(r) - 0.25\alpha & \text{if } \alpha - 2 \leq \phi(r) < \alpha \end{cases}$$

with $\phi(r) = \beta_0 + \beta_1 r + \beta_2 a + \beta_3 n + \beta_4 p + \beta_5 r_0$ and $\alpha$ a shifting parameter. More details on the use of the shifting parameter $\alpha$ will be given in Section 5.1. Also note that potential interaction terms in $\phi(r)$ have been omitted for ease of illustration. The desired properties of the response function $\tilde{R}(r, a, n, p)$ are, firstly, it is concave with respect to the price variable $r$ on the domain $\phi(r) \geq \alpha - 2$ and secondly, it intersects zero due to the linear function $0.5 + 0.25\phi(r) - 0.25\alpha$ that is tangent to the logistic function $1/(1 + e^{-\phi(r)+\alpha})$ in its inflection point. Figure 5 shows the effect of fitting the model $\tilde{R}(r, a, n, p)$ to the data. Statistical results (not provided here) showed that there is a marginal improvement in using this new adjusted response function compared to using the ordinary logit function in terms of goodness of fit.

It should be noted that although $\sum_{c \in C} I(r_c, a_c, n_c, p_c)\tilde{R}(r_c, a_c, n_c, p_c)$ is a concave objective function, obtaining an optimal solution poses a problem to most existing non-linear solvers due to the domain dependent definition of $R(r, a, n, p)$. In order to resolve the issue and to make it implementable for standard convex optimisation technology, a linearisation approach is followed whereby the new concave response function $\tilde{R}(r_c, a_c, n_c, p_c)$, for a customer segment $c \in C$, is approximated with piece-wise linear functions with respect to $r_c$. Let the support $0 \leq r_c \leq 1$ be divided into intervals indexed by $K = \{1, 2, \ldots, 1/w\}$ with $w$ the interval width. For each interval $k \in K$ the response function is approximated with a linear function having a slope of $m^R_{ck}$. In addition, the product $I(r_c, a_c, n_c, p_c)\tilde{R}(r_c, a_c, n_c, p_c)$ constituting the objective function for a customer segment $c \in C$, is approximated with linear functions with the slopes of these functions denoted by $m^I_{ck}$, $k \in K$. Introducing the incremental price variables $0 \leq r_{ck} \leq w$ and the take-up variables $t_c$ for each of the customer segments $c \in C$, the linear price optimisation problem (LPOP) is obtained:
max $\sum_{c \in C} \sum_{k \in K} m^c_k r_k$ \hfill (7)

s.t.

\begin{align*}
t_c &= \hat{R}(0, a_c, n_c, p_c) - \sum_{k \in K} m^{R}_{ck} r_k = 0 \quad \forall c \in C \\
t_c &\geq 0 \quad \forall c \in C \\
0 &\leq r_{ck} \leq w \quad \forall c \in C, \quad \forall k \in K
\end{align*} \hfill (8)\hfill (9)\hfill (10)

The above formulation of LPOP is a linear representation of a concave maximisation problem and solving it will produce an optimal solution $r^*_k$ for each $k \in K$ such that

$$\hat{R}(r^*_c, a_c, n_c, p_c) \approx \hat{R}(0, a_c, n_c, p_c) + \sum_{k \in K} m^{R}_{ck} r^*_k$$

and

$$\hat{I}(r^*_c, a_c, n_c, p_c) \hat{R}(r^*_c, a_c, n_c, p_c) \approx \hat{I}(0, a_c, n_c, p_c, v_c) \hat{R}(0, a_c, n_c, p_c) + \sum_{k \in K} m^{I}_{ck} r^*_k$$

with $r^*_c = \sum_{k \in K} r^*_{ck}$ for each customer segment $c \in C$. Although the take-up variables $t_c$ do not feature in the objective function they can now be used in other linear side constraints since their values depend on the optimal prices $r^*_c$.

4 A stochastic programming framework

To determine optimal price levels by considering the uncertainty in future price elasticity a two-stage stochastic programming approach is followed. The basic mechanism of this framework is to adjust the price to be quoted in such a way as to optimise net interest income expressed in terms of potential future realisations of response (see Higle (2005) for a very practical approach in explaining the two-stage mechanism). To achieve this a scenario based approach is followed whereby for each scenario $s \in \mathcal{S}$, with $\mathcal{S} = \{1, 2, \ldots, |\mathcal{S}|\}$ the index set of all scenarios, the following response function is fitted:

$$\hat{R}_s(r, a, n, p) = \begin{cases} 1/(1 + e^{-\phi(r,s)+\alpha}) & \text{if } \phi(r,s) \geq \alpha \\ 0.5 + 0.25\phi(r,s) - 0.25\alpha & \text{if } \alpha - 2 \leq \phi(r,s) < \alpha \end{cases} \hfill (11)$$

with $\phi(r,s) = \beta_0 + \beta_1 r + \beta_2 a + \beta_3 n + \beta_4 p + \beta_5 t_0$ (interaction terms not shown). The implication of adding a scenario index to the regression coefficients above is that uncertainty within future take-up rates is represented by a finite number of response functions $\hat{R}_s(r, a, n, p)$, with $s \in \mathcal{S}$. Obtaining different sets of betas for each of the scenarios $s \in \mathcal{S}$ can be accomplished in various ways. For instance, by using the partitioning in the above section that is based on the change in repurchase rate over time, a response function representative of the response behavior of customers within each time period can be estimated. In addition, hypothetical scenarios could be created to simulate potential future scenarios that may not be captured in existing data. A more detailed discussion on how this was done is provided in Section 5.

Keeping with the above notation, let $r_c \geq 0$ be the decision variable denoting the optimal price to quote customer segment $c \in C$. This variable is, within the context of stochastic programming, referred to as the first stage decision variable since the prices to be used in future quotes are determined up front. The scenario dependent take-up variables $t_{cs}$ are referred to as the second stage variables since their values depend on the possible future behaviour of customers as defined by the scenario dependent response functions $\hat{R}_s(r, a, n, p)$, with $s \in \mathcal{S}$.
The formulation of the credit price optimisation problem, as stated above, can now be reformulated as a stochastic programming problem by considering the following linearisations for each customer segment \( c \in \mathcal{C} \) and for each scenario \( s \in \mathcal{S} \):

\[
t_{cs} = \tilde{R}_s(r_c, a_c, n_c, p_c) \approx \tilde{R}_s(0, a_c, n_c, p_c) + \sum_{k \in \mathcal{K}} m^R_{cks} r_{ck}
\]

with \( m^R_{cks} \) the slopes of the linear functions approximating the response function and

\[
\tilde{I}(r_c, a_c, n_c, p_c) \tilde{R}_s(r_c, a_c, n_c, p_c) \approx \tilde{I}(0, a_c, n_c, p_c) \tilde{R}_s(0, a_c, n_c, p_c) + \sum_{k \in \mathcal{K}} m^I_{cks} r_{ck}
\]

with \( m^I_{cks} \) the slopes of the linear functions approximating the net interest income objective function. For both linearisations we have that \( r_c = \sum_{k \in \mathcal{K}} r_{ck} \). In order to state the complete credit price optimisation problem as a linear stochastic programming problem and to incorporate practical side constraints, some additional notation is required.

For ease of notation a risk grading \( g \in \mathcal{G} = \{1, 2, \ldots, |G|\} \) is a classification according to the average probability of default, allowing the definition of the index set \( \mathcal{C}(g) \) of all customer segments having a risk grading \( g \). Conversely, the mapping \( \mathcal{G}(c) \) can be used to retrieve the risk grading for a customer segment \( c \in \mathcal{C} \). The ordering \( g1 < g2 \) with \( g1 = \mathcal{G}(c1) \) and \( g2 = \mathcal{G}(c2) \) implies the ordering of the probabilities of default \( p_{c1} < p_{c2} \) with \( c1, c2 \in \mathcal{C} \). Furthermore, a similarity index \( h \in \mathcal{H} = \{1, 2, \ldots, |H|\} \) is assigned to each customer segment such that the index set \( \mathcal{C}(g, h) \) denote all the segments that have a risk grade of \( g \in \mathcal{G} \) and that are common with respect to loan amount and term, i.e. having the same similarity index \( h \in \mathcal{H} \). The mapping \( \mathcal{H}(c) \) can be used to retrieve the similarity index of a customer segment \( c \in \mathcal{C} \). For the purpose of imposing constraints on the retail credit price optimisation problem, the following additional parameters are required:

1. Let \( L_g \) denote the lower bound (in percentage) on the take-up volume of loans over all customer segments classified as having a risk grading \( g \in \mathcal{G} \).

2. Let \( U_g \) denote the upper bound (in percentage) on the take-up volume of loans over all customer segments classified as having a risk grading \( g \in \mathcal{G} \).

Let \( \rho_s \) denote the probability of response scenario \( s \in \mathcal{S} \) realising in future. The resulting stochastic linear price optimisation problem (SLPOP) is formulated as follows:

\[
\begin{align*}
\max & \quad \sum_{c \in \mathcal{C}} \sum_{s \in \mathcal{S}} \sum_{k \in \mathcal{K}} \rho_s m^I_{cks} r_{ck} \\
\text{s.t.} & \quad t_{cs} - \tilde{R}_s(0| a_c, n_c, p_c) - \sum_{k \in \mathcal{K}} m^R_{cks} r_{ck} = 0 \quad \forall c \in \mathcal{C}, \forall s \in \mathcal{S} (13) \\
& \quad \sum_{c \in \mathcal{C}(g, h)} r_{c} - \sum_{c \in \mathcal{C}(g+1, h)} r_{c} \leq 0 \quad \forall g \in \mathcal{G} \ if g < |G|, \forall h \in \mathcal{H} (14) \\
& \quad \sum_{c \in \mathcal{C}(g)} v_c t_{cs} - L_g \sum_{c \in \mathcal{C}} v_c t_{cs} \geq 0 \quad \forall g \in \mathcal{G}, \forall s \in \mathcal{S} (15) \\
& \quad \sum_{c \in \mathcal{C}(g)} v_c t_{cs} - U_g \sum_{c \in \mathcal{C}} v_c t_{cs} \leq 0 \quad \forall g \in \mathcal{G}, \forall s \in \mathcal{S} (16)
\end{align*}
\]

The objective function (12) maximises the expected net interest income over all scenarios \( s \in \mathcal{S} \) and customer segments \( c \in \mathcal{C} \) by adjusting the income function \( \tilde{I}(r_c, a_c, n_c, p_c) \) with the future take-up rate \( t_{cs} \) for a given price \( r_c \). The values of \( t_{cs} \) are approximated through the constraints (13).
The constraint set (14) ensures monotonicity among the optimal rates for different risk categories. For example, if two segments $c_1 \in C$ and $c_2 \in C$ are similar with respect to their loan amounts and terms, i.e. $H(c_1) = H(c_2)$, but $c_1$ has a lower risk classification compared to $c_2$, i.e. $G(c_1) \leq G(c_2)$, then the inequality $r_{c_1} \leq r_{c_2}$ should hold. The constraint sets (15) and (16) imposes a lower and upper limit on the total volume for each risk grading $g \in G$, over all the scenarios $s \in S$.

5 Optimisation results

In order to illustrate the benefit of casting the retail credit price optimisation problem into a two-stage stochastic programming framework, empirical tests were performed using the data already introduced in Section 2.

The response function $\tilde{R}_s(r, a, n, p)$ implies a set of betas being dependent on a scenario $s \in S$. As shown above, one way of creating a set of betas for each of the scenarios is by partitioning the data set into subsets and estimating for each subset a response function. For the empirical results that will follow two data sets were created. For the first data set, referred to as the expected scenario, no partitioning was done on the data and a single response function was fitted to the entire segmented data set, i.e. $S = \{1\}$ and the segment averages were used as input such that the number of cases were $|C|$. For the second data set, referred to as the repurchase rate scenarios, three scenarios were created based on the partitioning done according to Figure 3. Note, however, that there is not an exact mapping between the three scenarios and the three time periods depicted in Figure 3. The first scenario corresponds to the sensitivity towards price due to a rapid decrease in repurchase rate, i.e. the first time period. The second scenario, however, corresponds to the third time period and captures the sensitivity towards price due to a constant repurchase rate. Since our data set only includes historic periods where either a decrease in repurchase rate or a constant rate was observed, the third scenario was created artificially to represent a potential future scenario whereby an increase in repurchase rate is expected that could result in potential customers being more price sensitive. This was achieved by modifying the regression coefficients of the second scenario’s response function manually in order to make the take-up percentage much more sensitive towards price. Figure 6 shows the response graphs for the three repurchase rate scenarios that will be used as input to the SLPOP.

The SLPOP is formulated to cater for different customer segments in order to align with a
customer centric pricing approach. Customer segments were created from the same historic data used for the estimation of the response functions and it was done in a fashion that will simplify practical pricing implementation. That is, pricing tables in practice entails having predefined prices for equally spaced intervals of the required loan amount, term and probability of default to simplify price lookup for a prospective client. With equally spaced intervals at hand for each of the variables in the data set, each segment was then selected such that a unique combination of intervals is obtained for each of the variables. For example, let $B = \{1, 2, \ldots, |B|\}$ be the indices of the equally spaced intervals defined for the variables $a$, $n$ and $p$. The randomly selected sequence $\{b_a, b_n, b_p\}$ with $b_a, b_n, b_p \in B$ forms one combination of interval indices which could be used to denote a segment. For testing purposes a total of 1016 segments were used in this study.

The numerical work in this study was performed by using the software system SAS®. The estimation of the response functions (6) and (11) was done with maximum likelihood estimation using the SAS® procedure proc nlp. An effective way to speed up the maximum likelihood estimation procedure is to make use of the beta solutions obtained from fitting the original response function as defined in (1) as starting solutions. This can be done effectively using the SAS® procedure proc logistic. The optimisation of the SLPOP was achieved through the use of the SAS® mathematical programming environment proc optmodel.

The subsections below address different aspects of solving the SLPOP. In the first subsection the behaviour of the SLPOP as a result of using the expected response scenario is discussed. In the following subsection the basic mechanism of the two stage stochastic programming framework is illustrated by solving the SLPOP for the three repurchase rate scenarios.

### 5.1 Solving SLPOP for the expected response scenario

The SLPOP formulation reduces to a deterministic optimisation problem when using the expected response scenario obtained from fitting the response model (11) to the entire data set. Initial results, however, showed that unrealistically high prices are generated as optimal solutions. This suggests that the fitted function $\hat{R}_n(r, a, n, p)$ does not produce enough of a penalty effect on the net interest income. This could be attributed to the fact that the model in (11) does not take competitor information into account in representing price elasticity or that important variables may have been omitted. In an attempt to address this shortcoming the shifting parameter $\alpha$ in (11) is used to control the severity of how much the response function $\hat{R}_n(r, a, n, p)$ should penalise the net interest income with. The approach followed was to approximate the net interest income function (12) and the response function (13) of the SLPOP for different levels of $\alpha$ after fitting the model (11) with $\alpha = 0$.

Table 1 shows the results obtained by solving SLPOP for the expected scenario with different penalty levels of $\alpha$. The column “Average optimal prices” in Table 1 gives the optimal prices obtained for the risk gradings “LR”, “MR” and “HR”, which are risk categories defined for low risk, medium risk and high risk customers respectively. Let $r^*_c = \sum_{k \in K} x_n^{r,k}$ denote the optimal price obtained for customer segment $c \in C$ by solving the SLPOP to optimality, then the average optimal price per risk grading $g \in G$ is given by $(1/|C(g)|) \sum_{c \in C(g)} x_n^{r,k}$. The entries in the column “Take-up volumes” are calculated from the solutions to the take-up variables $t_n^{r,k}$. That is, the percentage of take-up volume for risk grade $g \in G$ relative to the total volume is given by $\sum_{c \in C(g)} v_c t_n^{r,k} / \sum_{c \in C} v_c t_n^{r,k}$, with $v_c$ the expected number of loan applications for customer segment $c \in C$.

The adjustment effect of the response function due to adverse selection is clearly noticeable by observing that lower optimal prices are obtained for the low risk customers compared to the high risk customers for all levels of $\alpha$. Furthermore, the penalty effect on the net interest income can clearly be observed since optimal prices across all three risk categories are reduced with an increase in $\alpha$. The choice of an optimal $\alpha$ to use will be determined by how realistic the proposed optimal prices are. One way of doing this is to consider the legal limit imposed on pricing retail

loans. Within the South African context the legal limit is given by the formula $2.2r_0 + 0.2$ with $r_0$ the repurchase rate. Considering that at the time of this study the repurchase rate was at 5%, the maximum allowable price legally is 31%. Therefore, the optimal $\alpha$ that will be used in the remainder of this paper will be $\alpha = 2.75$ since the optimal prices obtained are below the legal limit over all three risk categories. Limiting the prices could also be achieved by imposing an upper limit on the price variables $r_c$. However, the suggested penalty approach aims at controlling the severity of the response function while maintaining its functional form across different risk categories and different customer segments. This will not be achieved by only imposing an upper limit on the pricing variables.

### 5.2 Solving SLPOP for the repurchase rate scenarios

In order to show the benefit of using a stochastic programming framework evidence must be provided that show an improvement in net present income by solving the SLPOP with different scenarios compared to solving the SLPOP using only the expected scenario (which reduces the SLPOP to a simple deterministic optimisation problem). To achieve this a test was performed by which optimal prices $r_{ES}^c$, for each customer segment $c \in \mathcal{C}$, are obtained by solving the SLPOP with the expected scenario (ES) and by re-calculting the following objective function using the three repurchase rate scenarios:

$$\sum_{c \in \mathcal{C}} \sum_{s \in \mathcal{S}} \tilde{I}(r_{ES}^c, a_c, n_c, v_c, p_c, \delta) \tilde{R}_s(r_{ES}^c, a_c, n_c, p_c)$$ (17)

This was done to see if it would be reasonable to use the “expected” optimal prices in calculating the net present interest income for different realisations of future response scenarios. A desirable outcome, therefore, would be if the objective function value obtained by solving SLPOP over all three repurchase rate scenarios simultaneously, given by (18) below, is greater than the objective function value provided by (17):

$$\sum_{c \in \mathcal{C}} \sum_{s \in \mathcal{S}} \tilde{I}(r_{RSS}^c, a_c, n_c, v_c, p_c, \delta) \tilde{R}_s(r_{RSS}^c, a_c, n_c, p_c)$$ (18)

where $r_{RSS}^c$ are the optimal prices obtained by solving the SLPOP over all three repurchase rate scenarios (RSS) simultaneously. For subsequent empirical results the use of SLPOP requires the scenario probabilities $\rho_s$, for each scenario $s \in \mathcal{S}$. Table 2 provides three cases that relate to different repurchase rate scenarios and the associated scenario probabilities. For the first case we assume that the current repurchase rate is high and a meaningful future outcome is that the repurchase

</table>

rate will most likely decrease. For this case the probabilities of 60%, 20% and 20% are assigned to a decreasing, a constant and an increasing repurchase rate scenario respectively. For the case where the current repurchase rate is on an average historic level the probabilities of 20%, 60% and 20% are assigned to a decreasing, a constant and an increase repurchase rate scenario respectively, to indicate that we expect the repurchase rate to remain unchanged. For the final case a low current repurchase rate is assumed with the future expectation that it will increase, making it reasonable to assign the probabilities of 20%, 20% and 60% to a decreasing, a constant and an increasing repurchase rate scenario respectively.

Table 3 shows the optimisation results for the first case were we consider a high current repurchase rate with a high probability that it may decrease in future. The first row provides the average optimal prices for the low risk “LR”, medium risk “MR” and high risk “HR” categories respectively when solving SLPOP using all three repurchase rate scenarios simultaneously. For the same row the value in the column “Objective improvement” gives the percentage improvement obtained in solving the SLPOP with all three repurchase rate scenarios, compared to solving the SLPOP using only the expected scenario. That is, the percentage improvement is obtained by calculating the the relative improvement of (18) over (17). The improvement of 6.4% in net present interest income shows that the optimal prices obtained by solving the SLPOP over the three repurchase rate scenarios simultaneously are more robust compared to the “expected” optimal prices. By solving the SLPOP over all available scenarios simultaneously more information is taken into account and optimal prices are better balanced against the effect of scenario dependent take-up volumes that influence the objective function value. Continuing with the analysis of the second row of Table 3 we observe that the take-up volumes for the “HR” category for the first scenario represents about 50% of the total volume. For the third scenario, however, the proportion of high risk volume is almost

80% making it a very risky portfolio. It could be argued that since there is only a 20% probability of the third scenario realising in future that it may be acceptable. The SLPOP, however, does provide the capability to manage the portfolio risk by using the volume constraint sets (15) and (16). The second row of Table 3 gives the results for solving SLPOP using all three repurchase rate scenarios simultaneously, but with the constraint (16) imposing an upper limit of 50% on the high risk category volume. From the results it is clear that a price is paid in terms of the net interest income with the objective improvement now only at 5.3%. The benefit achieved however is an improved risk profile with the high risk category volume now limited to 50% for all three potential future scenarios.

Table 4 shows the optimisation results for the second case were we consider an average repurchase rate (compared historically) with a high probability that it will remain unchanged in future. Once again an improvement in objective function value is observed when solving the SLPOP over the three repurchase rate scenarios simultaneously. The first row shows an improvement of 10.6% but again with a risky portfolio if scenario three happen to realise in future. The second row of Table 4 shows the results for resolving SLPOP with the 50% limit on high risk volume with an improvement of 8.9% in net interest income obtained over solving the SLPOP with the expected scenario. It should be noted that, not only do we achieve an improvement in net interest income by solving the SLPOP over all three repurchase rate scenarios simultaneously, we are guaranteed that the scenario dependent take-up volumes adheres to the volume constraint, which is not necessarily the case for solving the SLPOP using the expected scenario.
Table 5 shows the optimisation results for the third case where we consider a low current repurchase rate with a high probability that there will be an increase in repurchase rate in the future. The improvements obtained in solving the SLPOP over the three repurchase rate scenarios simultaneously without and with the volume constraint are 20.9% and 20.2% respectively. These results show that meaningful results can be obtained for the credit price optimisation problem by considering hypothetical scenarios like we did with the inclusion of scenario three that represents a potential increase in repurchase rate, a situation that is not captured in the historical data available.

6 Summary and conclusion

The price optimisation problem addressed in this paper deals with determining the optimal prices to quote prospective customers while considering uncertainty in future price sensitivity. That is, the take-up rates of future loans may deviate from current levels necessitating the use of a stochastic programming approach. This study is, to the best of our knowledge, a first attempt to incorporate uncertainty in price sensitivity as part of an explicitly formulated mathematical programming problem.

In this study a concave response function is suggested that allows for the formulation of a linearised price optimisation problem that can be solved to optimality using standard linear programming technology. With a linear representation more complex formulations of the price optimisation problem can be handled such as volume constraints expressed in terms of the response function. The suggested response model also ensures a finite support for the pricing decision variable which makes it much more realistic compared to using a logit based response function with asymptotic properties.

The benefit of employing a stochastic programming approach was illustrated by means of empirical tests based on real data. Although some theoretical contributions have been made recently towards developing price optimisation models for retail credit, little evidence exist in literature of empirical work supporting the benefits of employing price optimisation technology. The results in this study showed that by only using “expected” optimal prices either a loss in revenue can occur due to lost opportunity, or a violation of strategic constraints can be expected when certain take-up scenarios realise in future.
