

Modal occupation measures and LMI relaxations for nonlinear switched systems control *

Mathieu Claeys¹, Jamal Daafouz², Didier Henrion^{3,4,5}

Draft of April 17, 2014

Abstract

This paper presents a linear programming approach for the optimal control of nonlinear switched systems where the control is the switching sequence. This is done by introducing modal occupation measures, which allow to relax the problem as a primal linear programming (LP) problem. Its dual linear program of Hamilton-Jacobi-Bellman inequalities is also characterized. The LPs are then solved numerically with a converging hierarchy of primal-dual moment-sum-of-squares (SOS) linear matrix inequalities (LMI). Because of the special structure of switched systems, we obtain a much more efficient method than could be achieved by applying standard moment/SOS LMI hierarchies for general optimal control problems.

1 Introduction

A switched system is a particular class of a hybrid system that consists of a set of dynamical subsystems, one of which is active at any instant of time, and a policy for activating and deactivating the subsystems. These dynamical systems are encountered in a wide variety of application domains such as automotive industry, power systems, aircraft and traffic control, and more generally the area of embedded systems. Switched systems have been the concern of much research, and many results are available for stability analysis

and control design. They put in evidence the importance of orchestrating the subsystems through an adequate switching strategy, in order to impose global stability and/or performance. Interested readers may refer to the survey papers [15, 30, 42, 32] and the books [31, 43] and the references therein.

In this context, these systems are generally controlled by intrinsically discontinuous control signals, whose switching rule must be carefully designed to guarantee stability and performance properties. As far as optimality is concerned, several results are available in two main different contexts:

- The first category of methods exploits necessary optimality conditions, in the form of Pontryagin’s maximum principle (the so-called indirect approaches), or through a large nonlinear discretization of the problem (the so-called direct approaches). The first contributions can be found in [7, 22, 33] where the problem has been formulated and partial solutions provided through generalized Hamilton-Jacobi-Bellman (HJB) equations or inequalities and convex optimization. In [35, 40, 41], the maximum principle is generalized to the case of general hybrid systems with nonlinear dynamics. The case of switched systems, switched piecewise affine systems and hybrid systems motivated from manufacturing environments is discussed in [4, 38, 10]. For general nonlinear problems and hence for switched systems, only **local optimality** can be guaranteed, even when discretization can be properly controlled [46]. The subject is still largely open and we are far from a complete and numerically tractable solution to the switched optimal control problem.
- The second category collects extensions of the performance indexes H_2 and H_∞ originally developed for linear time invariant systems without switching, and use the flexibility of Lyapunov’s approach, see for instance [20, 14] and references therein. Even for linear switched systems, the proposed results are based on nonconvex optimization problems (e.g. bilinear matrix inequality conditions) difficult to solve directly. Sufficient convex Linear Matrix Inequality (LMI) design conditions may be obtained, yielding computed solutions which are **suboptimal**, but at the price of introducing a conservatism (pessimism) and a gap to optimality which is hard, if not impossible, to evaluate. Since the computation of this optimal strategy is a difficult task, a suboptimal solution is of interest only when it is proved to be consistent, meaning that it imposes to the switched system a performance not worse than the one produced by each isolated subsystem [21].

Despite the interest of these existing approaches, the optimal control problem is not globally solved for switched systems, and new strategies are more than welcome, as computationally viable design techniques are missing. The present paper aims at complementing this rich literature on switched systems with convex programming techniques from the optimal control literature. Indeed, it is a well-known fact [44, 45] that optimal control problems can be relaxed as linear programming (LP) problems over measure spaces. Despite some early numerical results [36], this approach was merely of theoretic interest, before the advent of tractable primal-dual moment-sum-of-squares (SOS) **LMI hierarchies**, also now called Lasserre hierarchies, see [28] for an introduction to the subject. Most notably, [27] explores in depth the application of such a numerical method for general

polynomial optimal control problems, where the control is bounded. By modeling control and trajectory functions as *occupation measures*, one obtains a convex LP formulation of the optimal control problem. This infinite-dimensional LP can be solved numerically and approximately with a hierarchy of convex finite-dimensional LMIs.

In this paper, we consider the problem of designing optimal switching rules in the case of polynomial switched dynamical systems. Classically, we formulate the optimal control switching problem as an optimal control problem with controls being functions of time valued in the discrete set $\{0, 1\}$, and we relax it into a control problem with controls being functions of time valued in the interval $[0, 1]$. In contrast with existing approaches following this relaxation strategy, see e.g. [4, 34], relying on the *local* Pontryagin maximum principle, our aim is to apply the *global* approach of [27]. We show that by specializing the convex objects for switched systems, one obtains a numerical method for which the number of modes driving the system enters *linearly* into the complexity of the problem, instead of exponentially. On the one hand, our approach follows the optimal control modeling framework. On the other hand, it exploits the flexibility and computational efficiency of the convex LMI framework. In contrast with most of the existing work on LMI methods, we have a **guarantee of global optimality**, in the sense that we obtain an asymptotically converging (i.e. with vanishing conservatism) hierarchy of lower bounds on the achievable performance.

Organization of the paper

The paper is organized as follows. §2 constructs the generalized moment problem associated to the optimal control of switched systems, and details some conic duality results. These results are used in §3 to obtain an efficient numerical method based on the moment/SOS LMI hierarchy. §4 then outlines a simple sufficient optimality condition that is easy to check numerically. §5 gathers several useful extensions to the problem, kept separate from the main body of the article so as to ease exposition and notations. Finally, §6 illustrates the method on several examples.

Contributions

The contributions of this paper are as follows. On a theoretical level, a novel way of relaxing optimal control problems of switched systems is proposed, following [23]. The equivalence of this convex program with existing results in the literature [44, 45] is now rigorously proven. In addition, a full characterization of the dual conic problem as a system of relaxed HJB inequalities is given.

On a practical level, we present an easy to implement numerical method to solve the control problem, based on the LMI relaxations for optimal control [27]. The specialized measure LP formulation allows for substantial computational gains over generic formulations, which we now characterize. Up to our knowledge, this is one of the only results (along with [12] and [13]) exploiting problem structure for more efficient LMI relaxations of control problems.

Preliminaries

Let $\mathcal{M}(X)$ denote the vector space of finite, signed, Borel measures supported on an Euclidean subset $X \subset \mathbb{R}^n$, equipped with the weak-* topology, see e.g. [25] for background material. Let $\mathcal{M}^+(X)$ denote the cone of non-negative measures in $\mathcal{M}(X)$. The support of $\mu \in \mathcal{M}^+(X)$, the closed set of all points x such that $\mu(A) > 0$ for every open neighborhood A of x , is denoted by $\text{spt } \mu$. For $\mu \in \mathcal{M}(X)$, $\text{spt } \mu$ is the union of the supports of the Jordan decomposition of μ . For a continuous function $f \in \mathcal{C}(X)$, we denote by $\int_X f(x) \mu(dx)$ the integral of f w.r.t. the measure $\mu \in \mathcal{M}(X)$. When no confusion may arise, we note $\langle f, \mu \rangle = \int f \mu$ for the integral to simplify exposition and to insist on the duality relationship between $\mathcal{C}(X)$ and $\mathcal{M}(X)$. The Dirac measure supported at x^* , denoted by δ_{x^*} , is the measure for which $\langle f, \delta_{x^*} \rangle = f(x^*)$ for all $f \in \mathcal{C}(X)$. The indicator function of set A , denoted by $I_A(x)$, is equal to one if $x \in A$, and zero otherwise. The space of probability measures on X , viz. the subset of $\mathcal{M}^+(X)$ with mass $\langle 1, \mu \rangle = 1$, is denoted by $\mathcal{P}(X)$.

For multi-index $\alpha \in \mathbb{N}^n$ and vector $x \in \mathbb{R}^n$, we use the notation $x^\alpha := \prod_{i=1}^n x_i^{\alpha_i}$. We denote by \mathbb{N}_m^n the set of vectors $\alpha \in \mathbb{N}^n$ such that $\sum_{i=1}^n \alpha_i \leq m$. The moment of multi-index $\alpha \in \mathbb{N}^n$ of measure $\mu \in \mathcal{M}^+(X)$ is then defined as the real $y_\alpha = \langle x^\alpha, \mu \rangle$.

A multi-indexed sequence of reals $(y_\alpha)_{\alpha \in \mathbb{N}^n}$ is said to have a representing measure on X if there exists $\mu \in \mathcal{M}^+(X)$ such that $y_\alpha = \langle x^\alpha, \mu \rangle$ for all $\alpha \in \mathbb{N}^n$.

Let $\mathbb{R}[x]$ denote the ring of polynomials in the variables $x \in \mathbb{R}^n$, and let $\deg p$ denote the (total) degree of polynomial p .

A subset of \mathbb{R}^n is basic semi-algebraic if it is defined as the intersection of finitely many polynomial inequalities, namely $\{x \in \mathbb{R}^n : g_i(x) \geq 0, i = 1 \dots n_X\}$ with $g_i(x) \in \mathbb{R}[x]$, $i = 1 \dots n_X$.

Finally, we use the same notation x to denote indifferently trajectories $x(t)$ and state-space parameters, to simplify exposition. In particular, it is understood throughout the paper that a measure $\mu(dx)$, even if associated to a trajectory $x(t)$, is supported on an finite-dimensional Euclidean space and is not, say, a measure supported on an infinite-dimensional functional space.

2 Weak linear program

2.1 Problem statement

Consider the optimal control problem

$$\begin{aligned} \inf_{\sigma} \quad & \int_0^T l_{\sigma(t)}(t, x(t)) dt \\ \text{s.t.} \quad & \dot{x}(t) = f_{\sigma(t)}(t, x(t)), \quad \sigma(t) \in \{1, 2, \dots, m\}, \\ & x(0) = x_0, x(T) = x_T, (t, x(t)) \in [0, T] \times X \end{aligned} \tag{1}$$

where the infimum is w.r.t. sequence σ . The state x is a vector of n elements and the control consists in choosing, for almost all times, which of the m possible dynamics drives

the system. Throughout this section, the following assumptions hold:

Assumption 1 *Terminal time T is given. State constraint set X is given and compact. Let $K := [0, T] \times X$. Functions $f_j : K \mapsto \mathbb{R}^n$ (dynamics), and $l_j : K \mapsto \mathbb{R}$, $j = 1, \dots, m$ (Lagrangians) are given, continuous in all their variables, and Lipschitz continuous with respect to the state variable.*

Note that the above assumptions can be significantly weakened. For instance, mere measurability of the dynamics w.r.t. time, lower semi-continuity of the Lagrangian or unbounded state spaces when the Lagrangian is coercive are often considered in the calculus of variation literature. However, as §3 explores in depth, the question of the numerical representation of problem data is essential for rigorous *global* optimization. Up to our knowledge, only polynomials can offer such guarantees, and Assumption 1 is general enough to cover such an essential case.

Obviously, optimal control problem (1) can be equivalently written as

$$\begin{aligned} \inf_u \quad & \int_0^T \sum_{j=1}^m l_j(t, x(t)) u_j(t) dt \\ \text{s.t.} \quad & \dot{x} = \sum_{j=1}^m f_j(t, x(t)) u_j(t) \\ & x(0) = x_0, x(T) = x_T, (t, x(t)) \in K, u(t) \in U \end{aligned} \tag{2}$$

where the infimum is with respect to a time-varying vector $u(t)$ which belongs for all $t \in [0, T]$ to the (nonconvex) discrete set

$$U := \{(1, 0, \dots, 0), (0, 1, \dots, 0), \dots, (0, 0, \dots, 1)\} \subset \mathbb{R}^m. \tag{3}$$

The next sections explore the various ways this problem can be lifted/relaxed as a linear program over so-called *occupation measures*.

Remark 1 *Section 5 gathers several extensions to problem (1) for which the presented approach is applicable mutatis mutandis. This section is relegated at the end of the paper to ease exposition.*

2.2 Occupation measures

Simple examples (see for instance at the end of the paper) show that when measurable functions of time are considered for controls such as in (2), optimal solutions might not exist. This section summarizes several well-known concepts to regain compactness in the control. These tools will then be specialized in the next section for switched systems.

Definition 1 (Young measure) *A Young measure is a time-parametrized family of probability measures $\omega(du|t) \in \mathcal{P}(U)$ defined almost everywhere, such that for all test functions $v \in \mathcal{C}(U)$, the function $t \rightarrow \langle v, \omega \rangle$ is Lebesgue measurable.*

Young measures are also called generalized controls or relaxed controls, see for instance [19]. Note that classical controls $u(t)$, functions of time with values in U , are a particular case of Young measures for the choice $\omega(du|t) = \delta_{u(t)}(du)$. Following the terminology of [45], it is natural to relax (2) into the following “strong form”¹:

$$\begin{aligned}
p_S^* &= \inf_{\omega} \int_0^T \sum_{j=1}^m l_j(t, x(t)) u_j(t) dt \\
\text{s.t. } \dot{x} &= \left\langle \sum_{j=1}^m f_j(t, x(t)) u_j, \omega(du|t) \right\rangle \\
x(0) &= x_0, x(T) = x_T, (t, x(t)) \in K
\end{aligned} \tag{4}$$

where the infimum is w.r.t. a Young measure $\omega(du|t) \in P(U)$. Note that there might be a strict relaxation gap, viz. p_S^* is strictly less than the infimum in problem (1), for ill-posed instances. It is not the purpose of this article to explore such a non-generic case, and we refer to the discussion in e.g. [24, App. C] and the references therein on such occurrences. There are sufficient conditions guaranteeing the absence of such a gap, referred to as inward-pointing conditions, see for instance [18].

An equivalent way of relaxing (2) is to relax the controls to belong, for all $t \in [0, T]$, to the (convex) simplex

$$\text{conv } U = \{u \in \mathbb{R}^m : \sum_{j=1}^m u_j = 1, \quad u_j \geq 0, \quad j = 1, \dots, m\}. \tag{5}$$

In other words, problem (4) on Young measures is equivalent to replacing U with $\text{conv } U$ in problem (2). In [4], problem (4) is called the embedding of problem (1), and it is proved that the set of trajectories of problem (1) is dense (w.r.t. the uniform norm in the space of continuous functions of time) in the set of trajectories of embedded problem (4). Note however that these authors consider the more general problem of switching design in the presence of additional bounded controls in each individual dynamics. To cope with chattering effects due to the simultaneous presence of controls and (initial and terminal) state constraints, they have to introduce a further relaxation of the embedded control problem. In this paper, we do not have controls in the dynamics, and the only design parameter is the switching sequence.

Notice that once a Young measure $\omega(du|t)$ is given in problem (4), the corresponding state trajectory is uniquely determined by

$$x(t) = x_0 + \int_0^t \left\langle \sum_{j=1}^m f_j(s, x(s)) u_j, \omega(du|s) \right\rangle ds$$

and hence the following definition makes sense.

Definition 2 (Relaxed arc) *An admissible pair (x, ω) for problem (4) is called a relaxed arc.*

¹“Strong” is opposed here to the “weak” problem to be defined shortly after.

For optimization, strong problem (2) presents an essential first step, as sequential-compactness is regained, guaranteeing the existence of optimal solutions under the sole existence of a relaxed arc [45, Th. 1.2]. For *global* optimization though, the nonlinear dependence of (4) on trajectories $x(t)$ is problematic, and an additional generalization of Young measures must be introduced, capturing both controls *and* trajectories:

Definition 3 (Occupation measure) *Given a relaxed arc (x, ω) , its corresponding occupation measure is defined by*

$$\mu(A \times B \times C) := \int_A I_B(x(t)) \omega(C|t) dt$$

for all Borel subsets A, B, C of $[0, T]$, X and U , resp.

That is, occupation measures assign to each set $A \times B \times C$ the total time “spent” on it by a relaxed arc (x, ω) . An alternative definition could be

$$\mu(dt, dx, du) = \delta_{x(t)}(dx) \omega(du|t) dt.$$

By construction, an occupation measure satisfies

$$\langle v, \mu \rangle = \int_0^T \left(\int_U v(t, x(t), u) \omega(du|t) \right) dt \quad (6)$$

for all continuous test functions $v \in \mathcal{C}([0, T] \times X \times U)$. Indeed, by the Riesz representation theorem (see e.g. [25, §21.5]), an occupation measure could alternatively be defined as the unique measure satisfying (6) for all continuous test functions (recall the hypothesis of compact supports).

Evaluating now a continuously differentiable test function along a trajectory and making use of (6) reveals the following lemma:

Lemma 1 *Given a relaxed arc (x, ω) , its corresponding occupation measure satisfies the following linear constraints on its moments for any test function $v \in \mathcal{C}^1(\mathbb{R} \times \mathbb{R}^n)$:*

$$\left\langle \frac{\partial v}{\partial t} + \frac{\partial v}{\partial x} \cdot \sum_{j=1}^m f_j u_j, \mu \right\rangle = v(T, x_T) - v(0, x_0). \quad (7)$$

Note the use of a scalar product, denoted by a dot, between the gradient vector $\frac{\partial v}{\partial x}$ and the controlled dynamics. Rubio (see [36] and the references therein) proposed then to relax strong problem (4) by optimizing over all Borel measures satisfying (7) instead of simply occupation measures, yielding the following “weak” problem:

$$\begin{aligned} p_W^* &= \inf_{\mu} \left\langle \sum_{j=1}^m l_j(t, x(t)) u_j(t), \mu \right\rangle \\ \text{s.t.} & \left\langle \frac{\partial v}{\partial t} + \frac{\partial v}{\partial x} \cdot \sum_{j=1}^m f_j u_j, \mu \right\rangle = v(T, x_T) - v(0, x_0), \quad \forall v \in \mathcal{C}^1(K), \\ & \mu \in \mathcal{M}^+(K \times U). \end{aligned} \quad (8)$$

Weak problem (8) is rigorously justified by the following essential result [44]:

Theorem 1 *There is no relaxation gap between optimal control problem (4) and measure LP (8), viz.*

$$p_S^* = p_W^*. \quad (9)$$

Obviously, direction $p_S^* \geq p_W^*$ is a simple consequence of Lemma 1 and the continuity of the cost. The other direction, more involved, is the core of [44, 45]. Synthetically, the authors use specialized Hahn-Banach type separation arguments to show that the admissible set for weak problem (8) is the closure of the convex hull of the set of occupation measures of the admissible solutions of (4). That is, one could interpret those results as a Krein-Milman theorem for optimal control problems.

Note that the use of relaxations and LP formulations of optimal control problems (on ordinary differential equations and partial differential equations) is classical, and can be traced back to the work by L. C. Young, Filippov, as well as Warga and Gamkrelidze, amongst many others. For more details and a historical survey, see e.g. [17, Part III].

2.3 Modal occupation measures and primal LP

Occupation measures defined in §2.2 are supported on a subset of Euclidian space of dimension $n + m + 1$. As such, they prove to be challenging for practical numerical resolution when the size of the problem increases, a phenomenon known colloquially in the (dual) dynamic programming literature as the “curse of dimensionality”.

For instance, the numerical approach of [36] proposes to consider a finite subset of the countably many linear constraints on μ given by (7). Then, as a consequence of Tchakaloff’s theorem [28, Th. B.12], there exists an atomic measure with support included in that of μ , and satisfying the truncated linear constraints exactly. By gridding the support of μ with Dirac measures of unknown masses, one can then approach weakly- $*$ this atomic measure as the spatial resolution of the grid gets finer. This results in a finite-dimensional LP to solve, with a number $\mathcal{O}(1/\Delta^{n+m+1})$ of unknowns, with Δ the grid resolution. Therefore, for a fixed resolution, the size of the LP grows exponentially in the size of the state and control spaces.

Another example suffering a similar fate are LMI relaxations as presented later on in §3, which the authors prefer over LP approximations for their greater rigor – most noticeably the guarantee of obtaining lower bounds and their better convergence properties, see [28, Section 5.4.2]. Indeed, as shown in §3.4, for a given relaxation order, the size of the semi-definite blocks in the LMIs also grows exponentially with the dimension of the underlying space.

For finite-dimensional optimization problems, structural properties of the problem can be exploited to define equivalent LPs using more measures, but of smaller dimensions, see [29]. This allows for much faster numerical resolution. Motivated by these savings, we now introduce specialized occupation measures to satisfy much the same goal for the optimal control of switched systems:

Definition 4 (Modal occupation measures) *The j -th modal occupation measure $\mu_j(dt, dx) \in$*

$\mathcal{M}^+(K)$ associated with occupation measure μ as in Def. 3, is defined as

$$\mu_j(A \times B) := \int_A \int_B \int_U u_j \mu(dt, dx, du), \quad (10)$$

for all Borel subsets A, B of $[0, T]$, X , resp.

In words, modal occupation measures are the *projections* on $K = [0, T] \times X$ of the first moments of the occupation measure defined in §2.2 w.r.t. the controls. For each Borel subset of K , each modal occupation measure therefore specifies the time spent by the pair $(t, x(t))$ on each mode. As a consequence, Def. 4 implies the following specialization of Lem. 1 for switched systems:

Corollary 1 *Given a relaxed arc (x, ω) , its corresponding modal occupation measures satisfy the following linear constraints:*

$$\sum_{j=1}^m \left\langle \frac{\partial v}{\partial t} + \frac{\partial v}{\partial x} \cdot f_j, \mu_j \right\rangle = v(T, x_T) - v(0, x_0) \quad (11)$$

for all test functions $v \in \mathcal{C}^1(K)$.

Proof: Notice that by definition of U , the occupation measure satisfies

$$\left\langle \frac{\partial v}{\partial t}, \mu \right\rangle = \left\langle \frac{\partial v}{\partial t} \cdot \sum_{j=1}^m u_j, \mu \right\rangle. \quad (12)$$

The corollary is then the immediate application of Def. 4 and Fubini's theorem. \square

Corollary 1 naturally points to the following alternative weak problem for switched systems:

$$\begin{aligned} p^* &= \inf_{(\mu_1, \dots, \mu_m)} \sum_{j=1}^m \langle l_j, \mu_j \rangle \\ \text{s.t.} \quad &\sum_{j=1}^m \left\langle \frac{\partial v}{\partial t} + \frac{\partial v}{\partial x} f_j, \mu_j \right\rangle = v(T, x_T) - v(0, x_0), \quad \forall v \in \mathcal{C}^1(K), \\ &\mu_j \in \mathcal{M}^+(K), \quad j = 1, \dots, m \end{aligned} \quad (13)$$

where the minimization is w.r.t. the vector of modal occupation measures (μ_1, \dots, μ_m) .

This is rigorously justified by the following:

Theorem 2 *There is no relaxation gap between measure LP (8) and measure LP (13), viz.*

$$p^* = p_W^*$$

Proof: We first show $p^* \leq p_W^*$. Consider an admissible measure μ for (13). Then, by Cor. 1, there exists an admissible vector (μ_1, \dots, μ_m) satisfying (11). As the cost can be

treated in an analogous fashion, this shows that any admissible solution for (13) is also admissible for (8) with the same cost, hence $p^* \leq p_W^*$.

For the reverse inequality, consider now a vector (μ_1, \dots, μ_m) admissible for (8), and define

$$\bar{\mu} := \sum_{j=1}^m \mu_j. \quad (14)$$

By construction, each μ_j is absolutely continuous with respect to $\bar{\mu}$, such that by the Radon-Nikodým Theorem [25, §18.4], there exists a non-negative, measurable function $\bar{u}_j(t, x)$ such that $\mu_j = \bar{u}_j \bar{\mu}$. Injecting this back in (14) shows that, in addition, $\sum_{j=1}^m \bar{u}_j = 1$, $\bar{\mu}$ -almost everywhere. Define now $\mu \in \mathcal{M}^+(K \times U)$, with U as in (3), such that

$$\mu(dt, dx, du) := \left(\sum_{j=1}^m \bar{u}_j(t, x) \delta_1(du_j | t, x) \right) \bar{\mu}(dt, dx), \quad (15)$$

such that by definition:

$$\int_U u_j \mu(dt, dx, du) = \bar{u}_j(t, x) \bar{\mu}(dt, dx), \quad (16)$$

where the last two equations are understood in a weak sense. Working out the weak dynamics of (13) leads then to:

$$\begin{aligned} \sum_{j=1}^m \left\langle \frac{\partial v}{\partial t} + \frac{\partial v}{\partial x} \cdot f_j, \mu_j \right\rangle &= \sum_{j=1}^m \left\langle \left(\frac{\partial v}{\partial t} + \frac{\partial v}{\partial x} \cdot f_j \right) \bar{u}_j, \bar{\mu} \right\rangle \\ &= \left\langle \frac{\partial v}{\partial t} + \sum_{j=1}^m \frac{\partial v}{\partial x} \cdot f_j \bar{u}_j, \bar{\mu} \right\rangle \\ &= \left\langle \frac{\partial v}{\partial t} + \sum_{j=1}^m \frac{\partial v}{\partial x} \cdot f_j u_j, \mu \right\rangle. \end{aligned} \quad (17)$$

As the cost can be treated in a similar manner, this concludes $p^* \geq p_W^*$, hence the proof. \square

Theorem (2) fulfills the objective laid at the beginning of this section. Indeed structured LP (13) involves m modal occupation measures supported on spaces of dimension $n + 1$, instead of a single occupation measure on a space of dimension $n + m + 1$ as in unstructured LP (8).

2.4 HJB inequalities and dual LP

Before investigating the practical implications on LMI relaxations of structured measure LP (13), we explore its conic dual. This is an interesting result in its own right for so-called “verification theorems” which supply necessary and sufficient conditions in the form of more traditional HJB inequalities. In addition, practical numerical resolution of the

LMI relaxations by primal/dual interior-point methods [39] implies that a strengthening of this dual will be solved as well, as shown later on in §3.3.

In this section, it is first shown that the solution of (13) is attained whenever an admissible solution exists. Then, the dual problem of (13), in the sense of conic duality, is presented. This leads directly to a system of subsolutions of HJB equations. Although, the cost of this problem might not be attained, it is however shown that there is no duality gap between the conic programs.

First of all, we establish that whenever the optimal cost of (13) is finite, there exists a vector of measures attaining the value of the problem:

Lemma 2 *If p^* is finite in problem (13),*

there exists an admissible $(\mu_1^, \dots, \mu_m^*)$ attaining the infimum, viz. such that*

$$\sum_{j=1}^m \langle l_j, \mu_j^* \rangle = p^*. \quad (18)$$

Proof: We first show that the mass of each measure is bounded. This is true for each μ_j , since test function $v(t, x) = t$ imposes $\sum_{j=1}^m \langle 1, \mu_j \rangle = T$. Then, following Alaoglu's theorem [25, §15.1], the unit ball in the vector space of compactly supported measures is compact in the weak-* topology. Therefore, any sequence of admissible solutions for (13) possesses a converging subsequence. Since this must be true for any sequence, this is true for any minimizing sequence, which concludes the proof. \square

Now, remark that (13) can be seen as an instance of a conic program, called hereafter the primal, in standard form (see for instance [2]):

$$\begin{aligned} p^* &= \inf_{x_p} \langle x_p, c \rangle_p \\ &\text{s.t. } \mathcal{A} x_p = b, \\ &\quad x_p \in E_p^+ \end{aligned} \quad (19)$$

where

- decision variable $x_p := (\mu_1, \dots, \mu_m)$ belongs to vector space $E_p := \mathcal{M}(K)^m$ equipped with the weak-* topology;
- the cost $c := (l_1, \dots, l_m)$ belongs to vector space $F_p := \mathcal{C}(K)^m$ equipped with the strong topology;
- $\langle \cdot, \cdot \rangle_p : E_p \times F_p \rightarrow \mathbb{R}$ is the duality bracket given by the integration of continuous functions with respect to Borel measures, since $E_p = F_p'$, with the prime denoting the topological dual;
- the cone E_p^+ is the non-negative orthant of E_p ;
- the linear operator $\mathcal{A} : E_p \rightarrow \mathcal{C}^1(K)'$ is given by

$$x_p \mapsto \mathcal{A} x_p = \sum_{j=1}^m \mathcal{L}_j \mu_j \quad (20)$$

where \mathcal{L}_j is the adjoint operator of $\mathcal{L}'_j : \mathcal{C}^1(K) \rightarrow \mathcal{C}(K)$ defined by

$$v \mapsto \mathcal{L}'_j v := \frac{\partial v}{\partial t} + \frac{\partial v}{\partial x} \cdot f_j; \quad (21)$$

- right hand side $b := \delta_{(T, x_T)}(dt, dx) - \delta_{(0, x_0)}(dt, dx)$ belongs to vector space $E_d := \mathcal{C}^1(K)'$.

Lemma 3 *The conic dual of LP problem (13) is given by*

$$\begin{aligned} d^* &= \sup_v v(T, x_T) - v(0, x_0) \\ \text{s.t. } & l_j(t, x) - \mathcal{L}'_j v(t, x) \geq 0, \quad \forall (t, x) \in K, \quad j = 1 \dots m, \\ & v \in \mathcal{C}^1(K). \end{aligned} \quad (22)$$

Proof: Following standard results of conic duality (see [1] or [2]), the conic dual of (19) is given by

$$\begin{aligned} d^* &= \sup_{x_d} \langle b, x_d \rangle_d \\ \text{s.t. } & c - \mathcal{A}' x_d \in \mathcal{C}^+(K)^m, \\ & x_d \in E_d \end{aligned} \quad (23)$$

where

- decision variable $x_d := v$ belongs to vector space $F_d := \mathcal{C}^1(K)$;
- the (pre-)dual cone is $\mathcal{C}^+(K)^m$, i.e. E_p^+ is dual to $\mathcal{C}^+(K)^m$;
- $\langle \cdot, \cdot \rangle_d : E_d \times F_d \rightarrow \mathbb{R}$ is the appropriate duality pairing between E_d and F_d .

The lemma just details this dual problem. □

Once the duality relationship established, the question arises of whether a duality gap occur between linear problems (13) and (22). The following theorem discards such a possibility:

Theorem 3 *There is no duality gap between primal LP (13) and dual LP (22): if there is an admissible vector for (13), then*

$$p^* = d^*. \quad (24)$$

Proof: One can show, following [1, Th. 3.10] (see also the exposition in [2, §4]), that the closure of the cone

$$R := \{(\langle x_p, c \rangle_p, \mathcal{A} x_p) : x_p \in E_p^+\} \quad (25)$$

belongs to $\mathbb{R} \times E_d$. Note that the weak-* topology is implicit in the definition of E_d , and the closure of R should be understood in such a weak sense.

To prove closure, one may show that, for any sequence of admissible solutions $(x_p^{(n)})_{n \in \mathbb{N}}$, all accumulation points of $(\langle x_p^{(n)}, c \rangle_p, \mathcal{A} x_p^{(n)})_{n \in \mathbb{N}}$ belong to R . Note that Lemma 2 establishes

that any sequence $(x_p^{(n)})_{n \in \mathbb{N}}$ has a converging subsequence. Therefore, all that is left to show is the weak-* continuity of \mathcal{A} , hence of each \mathcal{L}_j . Following [27], this can be shown by noticing that each \mathcal{L}'_j is continuous for the strong topology of $\mathcal{C}^1(K)$, hence for its associated weak topologies. Operators \mathcal{L}'_j , hence \mathcal{A} , are therefore weakly-* continuous, and each sequence $(\langle x_p^{(n)}, c \rangle_p, \mathcal{A}x_p^{(n)})_{n \in \mathbb{N}}$ converges in R , which concludes the proof. \square

Note that what is not asserted in Th. 3 is the existence of a continuous function for which the optimal cost is attained in dual problem (22). Indeed, it is a well-known fact that value functions of optimal control problems, to which v is closely related, may not be continuous, let alone continuously differentiable. However, there does exist an admissible vector of measures for which the optimal cost of primal (13) is attained (whenever there exists an admissible solution), following Lemma 2. This gives practical motivations for working in a purely primal approach on measures, as the dual problem will be solved anyway as a side product, see in the later sections of this article.

We close this section by detailing how dual problem (22) can nonetheless be used analytically as a “verification theorem”, following the discussion of [44] for the unstructured case, that is following the dual of (13) instead.

Denote by τ_j the time subset for which the j -th mode is “active”:

$$\tau_j := \text{spt} \pi_t \mu_j, \quad (26)$$

where $\pi_t \mu_j$ is the projection, or marginal of μ_j on the time axis, viz. the unique measure such that

$$\langle v(t), \pi_t \mu_j \rangle = \int_K v(t) \mu_j(dt, dx) \quad (27)$$

for all continuous test functions v and $j = 1, \dots, m$. If an admissible control $u(t)$ is piecewise-continuous, then obviously $\tau_j := \int_0^T I_{\{e_j\}}(u(t)) dt$, where e_j is the j -th unit vector of \mathbb{R}^m . Note however that the intersection of several of the τ_j might be of positive Lebesgue measure. In this case, relaxed controls can only be weakly approximated by fast oscillating sequences of classical controls. In the language of differential inclusions, this consists of realizing a control in the convexified vector field but not belonging to the original vector field.

Corollary 2 *Let (x, ω) be a relaxed arc,*

and let the intervals τ_j be computed as in (26) from their occupation measures. Then there exists a sequence $(v_n)_{n \in \mathbb{N}} \in \mathcal{C}^1(K)$ admissible for (22), such that

$$\lim_{n \rightarrow \infty} \int_{\tau_j} (l_j(t, x(t)) - \mathcal{L}'_j v_n(t, x(t))) dt = 0, \quad j = 1, \dots, m, \quad (28)$$

if and only if (x, ω) is a globally optimal solution of optimal control problem (4).

Proof: This corollary explicits weak duality (via the complementarity condition $\langle x_p^*, c - \mathcal{A}'x_d^* \rangle_p = 0$) if x_p^* and x_d^* are optimal for their respective problems, and exploits Lem. 2 guaranteeing the existence of an optimal x_p^* . \square

The advantage of such specialized optimality certificates for switched systems over the general case is that the test needs only to be checked on a mode-by-mode basis. This is particularly true if mode-dependent constraints are introduced, see §5.2.

3 LMI relaxations

This section outlines the numerical method to solve (13) in practice, by means of primal-dual moment-SOS LMI relaxations. This is done by restricting the problem data to be polynomial, so that occupation measures can be equivalently manipulated by their moments for the problem at hand, see §3.1. Then, this new infinite-dimensional problem is truncated so as to obtain in §3.2 a convex, finite-dimensional relaxation, with dual described in §3.3. Finally, §3.4 shows how the structural properties of (13) improves the computational load of each of these relaxations in comparison to unstructured relaxations, as could be derived from (8).

In the remainder of the paper, the standing Assumption 1 is therefore strengthened as follows:

Assumption 2 *All functions are polynomial in their arguments:*

$$l_j, f_j \in \mathbb{R}[t, x], \quad j = 1, \dots, m. \quad (29)$$

In addition,

set $K = [0, T] \times X$ is basic semi-algebraic, viz. it is defined as the conjunction of finitely many polynomial inequalities

$$K = \{(t, x) \in \mathbb{R} \times \mathbb{R}^n : g_i(t, x) \geq 0, i = 1, \dots, n_K\} \quad (30)$$

with $g_i \in \mathbb{R}[t, x]$, $i = 1, \dots, n_K$. Let $g_0(t, x)$ denote the polynomial identically equal to one. In addition, it is assumed that one of the g_i enforces a ball constraint on all variables, which is possible w.l.g. since K is assumed compact (see [28, Th. 2.15] for slightly weaker conditions).

3.1 Moment LP

Given a sequence $y = (y_\alpha)_{\alpha \in \mathbb{N}^n}$, let $L_y : \mathbb{R}[x] \rightarrow \mathbb{R}$ be the Riesz linear functional

$$f(x) = \sum_{\alpha} f_{\alpha} x^{\alpha} \in \mathbb{R}[x] \quad \mapsto \quad L_y(f) = \sum_{\alpha} f_{\alpha} y_{\alpha}. \quad (31)$$

Define the *localizing matrix* of order d associated with sequence y and polynomial $g(x) = \sum_{\gamma} g_{\gamma} x^{\gamma} \in \mathbb{R}[x]$ as the real symmetric matrix $M_d(gy)$ whose entry (α, β) reads

$$[M_d(gy)]_{\alpha, \beta} = L_y(g(x) x^{\alpha+\beta}) \quad (32)$$

$$= \sum_{\gamma} g_{\gamma} y_{\alpha+\beta+\gamma}, \quad \forall \alpha, \beta \in \mathbb{N}_d^n. \quad (33)$$

In the particular case that $g(x) = 1$, the localizing matrix is called the *moment matrix*.

The construction of the LMI associated with problem (13) can now be stated. Its decision variable is the aggregate sequence of moments $y = (y_1, y_2, \dots, y_m)$ where each $y_j = (y_{j, \beta})_{\beta \in \mathbb{N}^{n+1}}$ is the moment sequence of measure $\mu_j(dt, dx)$ for $j = 1, 2, \dots, m$, i.e.

$$y_{j, \beta} = \langle v_{\beta}(t, x), \mu_j \rangle \quad (34)$$

for the particular choice of test function

$$v_\beta(t, x) := t^{\beta_0} x_1^{\beta_1} x_2^{\beta_2} \cdots x_n^{\beta_n}, \quad \beta \in \mathbb{N}^{n+1}. \quad (35)$$

As each term of the cost of (13) is polynomial by assumption, they can be rewritten as

$$\sum_{j=1}^m \sum_{\beta \in \mathbb{N}^{n+1}} c_{j,\beta} y_{j,\beta} = \sum_{j=1}^m L_{y_j}(l_j). \quad (36)$$

That is, vector $(c_{j,\beta})_\beta$ contains the coefficients of polynomials l_j expressed in the monomial basis. Similarly, the weak dynamics constraints of (13) need only be satisfied for countably many polynomial test functions, since the measures are supported on compact subsets of \mathbb{R}^{n+1} . Hence the weak dynamics defines a linear constraint between moments of the form

$$\sum_{j=1}^m \sum_{\beta \in \mathbb{N}^{n+1}} a_{j,\alpha,\beta} y_{j,\beta} = b_\alpha = v_\alpha(T, x_T) - v_\alpha(0, x_0) \quad (37)$$

where coefficients $a_{j,\alpha,\beta}$ can be deduced by identification from

$$\sum_{\beta \in \mathbb{N}^{n+1}} a_{j,\alpha,\beta} y_{j,\beta} = L_{y_j}(\mathcal{L}'_j v_\alpha), \quad \alpha \in \mathbb{N}^{n+1}. \quad (38)$$

Finally, the only nonlinear constraints are the convex LMI constraints for measure representativeness, i.e. constraints on y such that (34) holds for all $j = 1, \dots, m$ and $\beta \in \mathbb{N}^{n+1}$. Indeed, it follows from Putinar's theorem [28, Theorem 3.8] that the sequence of moments y has a representing measure defined on a set satisfying Assumption 2 if and only if $M_d(g_i y) \succeq 0$ for all $d \in \mathbb{N}$ and for all polynomials g_i defining the set, $i = 0, 1, \dots, n_K$, and where $A \succeq 0$ stands for matrix A positive semidefinite, i.e. with nonnegative real eigenvalues.

This leads to the problem:

$$\begin{aligned} p_\infty^* &= \inf_y \sum_{j=1}^m \sum_{\beta \in \mathbb{N}^{n+1}} c_{j,\beta} y_{j,\beta} \\ \text{s.t.} \quad &\sum_{j=1}^m \sum_{\beta \in \mathbb{N}^{n+1}} a_{j,\alpha,\beta} y_{j,\beta} = b_\alpha, \quad \alpha \in \mathbb{N}^{n+1}, \\ &M_d(g_i y_j) \succeq 0, \quad i = 0, 1, \dots, n_K, \quad j = 1, \dots, m, \quad d \in \mathbb{N}. \end{aligned} \quad (39)$$

Theorem 4 *Measure LP (13) and infinite-dimensional LMI problem (39) share the same optimum:*

$$p^* = p_\infty^*. \quad (40)$$

For the rest of the paper, we will therefore use p^* to denote the cost of measure LP (13) or LMI problem (39) indifferently.

3.2 Moment LMI hierarchy

The final step to reach a tractable problem is relatively obvious: infinite-dimensional LMI problem (39) is truncated to its first few moments.

To streamline exposition, first notice in LMI (39) that $M_{d+1}(\cdot) \succeq 0$ implies $M_d(\cdot) \succeq 0$, such that when truncated, only the constraints of highest order must be taken into account. Now, let $d_0 \in \mathbb{N}$ be the smallest integer such that all Lagrangians, dynamics and constraint monomials belong to $\mathbb{N}_{2d_0}^{n+1}$. This is the degree of the so-called *first relaxation*. For any relaxation order $d \geq d_0$, the decision variable is now the vector $(y_{j,\alpha})_\alpha$ with $\alpha \in \mathbb{N}_{2d}^{n+1}$, made of the first $\binom{n+2d+1}{n+1}$ moments of each measure μ_j . Then, define the index set

$$\bar{\mathbb{N}}_{2d}^{n+1} := \{ \alpha \in \mathbb{N}^{n+1} : \deg \mathcal{L}'_j v_\alpha \leq 2d, j = 1, \dots, m \},$$

viz. the set of monomials for which test functions of the form (35) lead to linear constraints of appropriate degree. By assumption, this set is finite and not empty – the constant monomial always being a member.

Then, the LMI relaxation of order d is given by

$$\begin{aligned} p_d^* &= \inf_y \sum_{j=1}^m \sum_{\beta \in \mathbb{N}_{2d}^{n+1}} c_{j,\beta} y_{j,\beta} \\ \text{s.t.} \quad &\sum_{j=1}^m \sum_{\beta \in \mathbb{N}_{2d}^{n+1}} a_{j,\alpha,\beta} y_{j,\beta} = b_\alpha, \alpha \in \bar{\mathbb{N}}_{2d}^{n+1} \\ &M_d(g_i y_j) \succeq 0, i = 0, 1, \dots, n_K, j = 1, \dots, m. \end{aligned} \tag{41}$$

Notice that for each relaxation, we get a standard LMI problem that can be solved numerically by off-the-shelf software. In addition, the relaxations converge asymptotically to the cost of the moment LP:

Theorem 5

$$p_{d_0}^* \leq p_{d_0+1}^* \leq \dots \leq p_\infty^* = p^*. \tag{42}$$

Proof: By construction, observe that $j > i$ implies $p_{d_0+j}^* \geq p_{d_0+i}^*$, viz. the sequence p_d^* is monotonically non-decreasing. Asymptotic convergence to p^* follows from [28, Theorem 3.8] as in the proof of Theorem 4. \square

Therefore, by solving the truncated problem for ever greater relaxation orders, we obtain a monotonically non-decreasing sequence of lower bounds to the true optimal cost.

3.3 SOS LMI hierarchy

As for the measure LP of §2, the moment LMI relaxations detailed in the previous section possess a conic dual. In this section, we show that this dual problem can be interpreted as a polynomial SOS strengthening of the dual outlined in §2.4. The exact form of the dual

problem is an essential aspect of the numerical method, since it will be solved implicitly whenever primal-dual interior-point algorithms are used for solving the moment LMI hierarchy of §3.2.

Let \mathbb{S}^n be the space of symmetric $n \times n$ real matrices. One can show (see e.g. [28, §C]) that, for $A, B \in \mathbb{S}^n$, $\langle A, B \rangle := \text{trace } AB$ is a duality bracket $\mathbb{S}^n \times \mathbb{S}^n \mapsto \mathbb{R}$, and that $\{A \in \mathbb{S}^n : A \succeq 0\}$ defines a convex cone of \mathbb{S}^n . In problem (41), let us define the matrices $A_{i,\beta} \in \mathbb{S}^{\binom{n+d+1}{n+1}}$ satisfying the identity

$$M_d(g_i y) = \sum_{\beta} A_{i,\beta} y_{\beta} \quad (43)$$

for every sequence $(y_{\beta})_{\beta}$ and $i = 0, 1, \dots, n_K$.

Proposition 1 *The conic dual of moment LMI problem (41) is given by the SOS LMI problem*

$$\begin{aligned} & \sup_{z, Z} \sum_{\alpha \in \mathbb{N}_{2d}^{n+1}} b_{\alpha} z_{\alpha} \\ & \text{s.t.} \quad \sum_{\alpha \in \mathbb{N}_{2d}^{n+1}} a_{j,\alpha,\beta} z_{\alpha} + \sum_{i=0}^{n_K} \langle A_{i,\beta}, Z_{i,j} \rangle = c_{j,\beta}, \quad \beta \in \mathbb{N}_{2d}^{n+1}, \\ & \quad Z_{i,j} \succeq 0, \quad i = 0, 1, \dots, n_K, \quad j = 1, \dots, m. \end{aligned} \quad (44)$$

Proof: Replacing the equality constraints in (41) as two inequalities, it is easy to see that the moment relaxation can be written as an instance of LP (23), whose dual is given symbolically by (19). Working out the details leads to the desired result, using for semi-definite constraints the duality bracket as explained earlier. \square

The relationship between (44) and (22) might not be obvious at a first glance. Denote by $\Sigma[z]$ the subset of $\mathbb{R}[z]$ that can be expressed as a finite sum of squares of polynomials. Then a standard interpretation (see e.g. [28]) of (44) in terms of such objects is given by the next proposition.

Proposition 2 *LMI problem (44) can be stated as the following polynomial SOS strengthening of problem (22):*

$$\begin{aligned} & \sup \quad v(T, x_T) - v(0, x_0) \\ & \text{s.t.} \quad l_j - \mathcal{L}'_j v = \sum_{i=0}^{n_K} g_i s_{i,j}, \quad j = 1, \dots, m \end{aligned} \quad (45)$$

where the maximization is w.r.t. the vector of coefficients z of polynomial

$$v(t, x) = \sum_{\alpha \in \mathbb{N}_{2d}^{n+1}} z_{\alpha} v_{\alpha}(t, x)$$

and the vectors of coefficients of polynomials

$$s_{i,j} \in \Sigma[t, x], \quad \deg g_i s_{i,j} \leq 2d, \quad i = 0, \dots, n_K, \quad j = 1, \dots, m.$$

Proof: By (37), the cost of (45) is equivalent to (44). Then multiply each scalar constraint (indexed by α) by v_α as given by (35), and sum them up. By definition, $\sum_\alpha c_{j,\alpha} v_\alpha = l_j$, and similarly, $\sum_\beta a_{j,\alpha,\beta} z_\alpha v_\alpha = \mathcal{L}'_j v_\alpha$. The conversion from the semi-definite terms to SOS exploits their well-known relationship (e.g. [28, §4.2]) to obtain the desired result, by definition (32) of the localizing matrices. \square

Prop. 2 specifies in which sense “polynomial SOS strengthenings” must be understood: positivity constraints of (22) are enforced by SOS certificates, and the decision variable of (22) is now limited to polynomials of appropriate degrees.

Finally, the following result states that no numerical troubles are expected when using classical interior-point algorithms on the primal-dual LMI pair (41-44).

Proposition 3 *The infimum in primal LMI problem (41) is equal to the supremum in dual LMI problem (44), i.e. there is no duality gap.*

Proof: By Assumption 2, one of the polynomials g_i in the description of set K enforces a ball constraint. The corresponding localizing constraint $M_d(g_i y_j) \succeq 0$ then implies that the vector of moments y is bounded in LMI problem (41). Then to prove the absence of duality gap, we use the same arguments as in the proof of Theorem 4 in Appendix D of [24]. \square

3.4 Computational complexity

This section details rough estimates on the numerical gains expected by employing modal occupation measures in LMI relaxations as opposed to the more generic method developed in [27].

Following the standing assumptions, the computational complexity of solving an LMI relaxation of order d with \bar{p} occupation measures supported on a space of dimension $n + m + 1$ (time, states, controls) is dominated by \bar{p} LMI constraints of size \bar{m} (the moment matrices of the occupation measures) in \bar{n} variables (the moment vectors of the occupation measures), with

$$\bar{n} = \binom{n + m + 2d + 1}{n + m + 1}, \quad \bar{m} = \binom{n + m + d + 1}{n + m + 1}. \quad (46)$$

A standard primal-dual interior-point algorithm to solve this LMI at given relative accuracy $\epsilon > 0$ (duality gap threshold) requires a number of iterations (Newton steps) growing as $\mathcal{O}(\bar{p}^{\frac{1}{2}} \bar{m}^{\frac{1}{2}}) \log \epsilon$, see e.g. [5, Section 6.6.3]. In the real model of computation (for which each addition, subtraction, multiplication, division of real numbers has unit cost), each Newton iteration requires no more than $\mathcal{O}(\bar{n}^3) + \mathcal{O}(\bar{p}\bar{n}^2\bar{m}^2) + \mathcal{O}(\bar{p}\bar{n}\bar{m}^3)$ operations. When solving a hierarchy of simple LMI relaxations as described above, the accuracy ϵ is fixed, the number of states n and controls m are fixed the number \bar{p} of measures is fixed, and the relaxation order d varies, such that $\mathcal{O}(\bar{n}) = \mathcal{O}(\bar{m}) = \mathcal{O}(d^{A(n+m+1)})$ and the dominating term in the complexity estimate grows in $\mathcal{O}(\bar{p}^{\frac{3}{2}} d^{\frac{9}{2}(n+m+1)})$, which clearly shows a strong dependence on the number of state and control variables.

Therefore, an LMI relaxation of an optimal switching control problem with n states and m controls will be solved in $\mathcal{O}(d^{\frac{9}{2}(n+m+1)})$ operations when solved with the general formulation of [27] and $\mathcal{O}(m^{\frac{3}{2}} d^{\frac{9}{2}(n+1)})$ when solved with structured formulation (13). That is a $\frac{n+1}{n+m+1}$ reduction of the polynomial rate at which the CPU time grows with relaxation orders. This back-of-the-envelope estimation is slightly conservative in practice, as shown in Ex. 6.2. Note that the same analysis as performed with the reported computation times of [6] or [37] reveals a similar underestimation of actual computation gains by applying the method described in this paper. As seen in these examples, those gains are substantial and justify the practical use of the modal occupation measures for switched systems.

4 Simple sufficient optimality conditions

As much as the necessary and sufficient conditions of §2.4 may be useful on small analytic examples, they are not exploitable numerically. We therefore present here a procedure for extracting piecewise constant controls, which are frequently observed in applications, see e.g. the examples of §6.

Indeed, suppose that the relaxed optimal control $\omega^*(du|t)$ is unique and has piecewise constant density:

$$\int_U \omega^*(du|t) dt = u(t) dt := \sum_{k=1}^N u_k I_{]t_{k-1}, t_k[}(t) dt$$

where this equation is understood in the weak sense. Assume w.l.g. (since controls need only to be defined almost everywhere) that the boundary conditions $u^*(0) = u^*(T) = 0$ hold. The Radon-Nikodým derivative of this piecewise constant control is then a train of Dirac impulses located at the switching times:

$$du(t) = \sum_{k=1}^N (u_{k+1} - u_k) \delta_{t_k}(dt)$$

where δ_{t_k} denotes the Dirac measure at $t = t_k$ and the equation is understood in the weak sense. As such atomic measures can be detected easily numerically, this motivates the following necessary conditions.

Proposition 4 *Let*

$$y_{j,\alpha} := \langle t^\alpha, \mu_j \rangle, \dot{y}_{j,\alpha} := \langle t^\alpha, \dot{\mu}_j \rangle, \alpha \in \mathbb{N}$$

denote the moments of modal occupation measure μ_j and the moments of its weak derivative $\dot{\mu}_j$, for $j = 1, \dots, m$. Then by construction

$$\dot{y}_{j,\alpha} = -\alpha y_{j,\alpha-1}, \alpha \in \mathbb{N}. \quad (47)$$

Let $\dot{M}_{j,d}$ be the truncated moment matrix – as defined in (32) for g equal to one – constructed from moment vector $(\dot{y}_{j,\alpha})_{\alpha=0,1,\dots,2(d-1)}$ as given by (47), with $d \geq 2$ and $j = 1, \dots, m$. The following result by Curto and Fialkow (see e.g. [28]) allows to detect those weak derivatives which can be written as train of impulses:

Theorem 6 (Flat extensions) *Let $r = \text{rank } \dot{M}_{j,d-1} = \text{rank } \dot{M}_{j,d-2}$. Then, there exists an r atomic measure supported on $[0, T]$ whose first moments match the vector $(\dot{y}_{j,\alpha})_{\alpha=0,1,\dots,2(d-1)}$.*

Note that the linear algebra routine presented in [28, §4.3] allows for the actual reconstruction of the times t_k (support) and jumps u_k (weight) represented by such a measure.

Corollary 3 (Simple sufficient optimality conditions) *For a given relaxation, let the rank condition of Th. 6 be satisfied, and let the reconstructed piecewise constant control strategy be admissible for (4), with cost matching that of the relaxation. Then the strategy is globally optimal.*

More generally, the reader interested in numerical methods for reconstructing a measure from the knowledge of its moments is referred to [26] and references therein, as well as to the recent works [16, 3, 9] which deal with the problem of reconstructing a piecewise-smooth function from its Fourier coefficients. To make the connection between moments and Fourier coefficients, let us just mention that the moments $y_\alpha = \int t^\alpha u(t) dt$ of a smooth density $u(t)$ are (up to scaling) the Taylor coefficients of the Fourier transform $\hat{u}(s) := \int e^{-2\pi i s t} u(t) dt = \sum_\alpha \frac{(-2\pi i)^\alpha}{\alpha!} y_\alpha s^\alpha$. If the y_α are given, then $\hat{u}(s)$ is given by its Taylor series, and the density $u(t)$ is recovered with the inverse Fourier transform $u(t) = \int e^{2\pi i s t} \hat{u}(s) ds$. Numerically, an approximate density can be obtained by applying the inverse fast Fourier transform to the (suitably scaled) vector $(y_\alpha)_{\alpha=0,1,\dots,2d}$ of moments.

5 Extensions

Several standard extensions of our results are now presented.

5.1 Free/distributed initial state

The approach can easily take into account a free initial state and/or time, by introducing an initial occupation measure $\mu_0 \in \mathcal{M}^+(\{0\} \times X_0)$, with $X_0 \subset \mathbb{R}^n$ a given compact set, such that for an admissible starting point $(t_0, x(t_0))$,

$$\langle v, \mu_0 \rangle = v(t_0, x(t_0)), \quad (48)$$

for all continuous test functions $v(t, x)$ of time and space. That is, in weak problem (13), one replaces some of the boundary conditions by injecting (48) and making μ_0 an additional decision variable. In dual (22), this adds a constraint on the initial value and modifies the cost.

Similarly, a terminal occupation measure μ_T can be introduced for free terminal states and/or time. Note that injecting both (48) and its terminal counterpart in (13) requires the introduction of an additional affine constraint to exclude trivial solutions, e.g. $\langle 1, \mu_0 \rangle = 1$ so that μ_0 is a probability measure. In dual problem (22), this introduces an additional decision variable.

More interestingly, the initial time may be fixed w.l.g. to $t_0 = 0$, but only the spatial probabilistic distribution of initial states is known. Let $\xi_0(dx) \in \mathcal{P}(X_0)$ be the measure whose law describes such a distribution. Then, the additional constraints for (13) are

$$\langle v, \mu_0 \rangle = \int_{X_0} v(0, x) \xi_0(dx). \quad (49)$$

As remarked in [27], this changes the interpretation of LP (13) to the minimization of the expected value of the cost given the initial distribution. See also [24] for the Liouville interpretation of the LP as transporting measure ξ_0 along the optimal flow.

5.2 Additional constraints

In measure LP (13), each modal occupation measure is supported on the same set K . This simply translates the fact that state constraints are mode-independent. However, nothing prevents the use of specific mode constraints by defining m sets $\{K_j\}_{j=1,\dots,m}$. In unstructured LP (8), these would be specified by constraining the support of μ to $\prod_{j=1}^m \{e_j\} \times K_j$, where e_j is the unit vector in \mathbb{R}^m whose j -th entry is 1. Then, in the proof of Th. 2, for direction $p^* \leq p_W^*$, it is easy to see that this implies that each μ_j is supported on K_j . For the reverse direction, one can define w.l.g. the support of $\bar{\mu}$ to be $K := \cup_{j=1}^m K_j$ by extending that of each μ_j to K and setting $\mu_j(K \setminus K_j) = 0$. Then μ has the expected support.

5.3 Wider class of dynamical systems

First note that additional drift terms, viz. dynamics of the form $\dot{x} = f_0 + \sum_{j=1}^m f_j u_j$, fit easily within the framework of problem (1) by adding the drift term to each mode dynamics.

Secondly, in a related fashion, affine-in-the-control problems with polytopic control sets more general than the box described in (5) can also be handled by the formalism presented in this paper. Indeed, the problem is equivalent to controlling (with relaxed objects – see section §2) the system with modes associated to vertices of the control polytope.

Finally, dynamics of the form $f_j(t, x(t), u_j(t))$, parametrized by a mode-dependent measurable control $u_j(t)$, can be incorporated into the presented formalism by combining the approach in this paper with that of [27]. However, mode-dependent states, where the size of the state-space varies for each given mode change and/or whose meaning is mode-dependent, must be incorporated by extending those states to all modes with a null vector field. It is an open question whether a more elegant approach can be incorporated into the framework of this paper.

5.4 Open-loop versus closed-loop

In problem (1), the control signal is the switching sequence $\sigma(t)$ which is a function of time: this is an open-loop control, similarly to what was proposed in [12] for impulsive

control design. One could also want to constrain the switching sequence to be an explicit or implicit function of the state, i.e. $\sigma(x(t))$, a closed-loop control signal. In this case, each occupation measure, explicitly depending on time, state and control, may be disintegrated as $\mu(dt, dx, du) = \xi(dt | t, u)\omega(du | t)dt$, and we should follow the framework described originally in [27].

5.5 Switching and impulsive control

We may also combine switching control and impulsive control if we extend the system dynamics to

$$dx(t) = \sum_{k=1}^m f_k(x(t)) u(t) dt + \sum_{j=1}^p g_j(t) \nu_j(dt),$$

which must be understood in a weak sense. Here, g_j are given continuous vector functions of time and ν_j are signed measures to be found, jointly with the switching signal $u(t)$. Whereas modal occupation measures are restricted to be absolutely continuous w.r.t. the Lebesgue measure of time, impulsive control measures ν_j can concentrate in time. For example, for a dynamical system $dx(t) = g(t)\nu(dt)$, a Dirac measure $\nu(dt) = \delta_s$ enforces at time $t = s$ a state jump $x^+(s) = x^-(s) + g(s)$. In this case, to avoid trivial solutions, the objective function should penalize the total variation of the impulsive control measures, see [12].

6 Examples

6.1 Chattering

Consider the scalar ($n = 1$) optimal control problem (1):

$$\begin{aligned} p^* &= \inf \int_0^1 x^2(t) dt \\ \text{s.t. } &\dot{x}(t) = a_{\sigma(t)} x(t), \\ &x(0) = \frac{1}{2}, \quad x(1) \in [-1, 1] \\ &x(t) \in [-1, 1], \quad \forall t \in [0, 1] \end{aligned}$$

where the infimum is w.r.t. to a switching sequence $\sigma : [0, 1] \mapsto \{1, 2\}$ and

$$a_1 := -1, \quad a_2 := 1.$$

In Table 1 we report the lower bounds p_d^* on the optimal value p^* obtained by solving LMI relaxations (41) of increasing orders d , rounded to 5 significant digits. We also indicate the number of variables \bar{n} (i.e. total number of moments) of each LMI problem, as well as the zeroth order moment of each occupation measure (recall that these are approximations of the time spent on each mode). We observe that the values of the lower bounds and the masses stabilize quickly.

In this simple case, it is easy to obtain analytically the optimal switching sequence: it consists of driving the state from $x(0) = \frac{1}{2}$ to $x(\frac{1}{2}) = 0$ with the first mode, i.e.

d	p_d^*	\bar{n}	$y_{1,0}$	$y_{2,0}$
1	$-5.9672 \cdot 10^{-9}$	18	0.74056	0.25944
2	$4.1001 \cdot 10^{-2}$	45	0.75170	0.24830
3	$4.1649 \cdot 10^{-2}$	84	0.74632	0.25368
4	$4.1666 \cdot 10^{-2}$	135	0.74918	0.25082
5	$4.1667 \cdot 10^{-2}$	198	0.74974	0.25026
6	$4.1667 \cdot 10^{-2}$	273	0.74990	0.25010
7	$4.1667 \cdot 10^{-2}$	360	0.74996	0.25004

Table 1: Lower bounds p_d^* on the optimal value p^* obtained by solving LMI relaxations of increasing orders d ; \bar{n} is the number of variables in the LMI problem; $y_{j,0}$ is the approximate time spent on each mode $j = 1, 2$.

$u_1(t) = 1, u_2(t) = 0$ for $t \in [0, \frac{1}{2}[$, and then chattering between the first and second mode with equal proportion so as to keep $x(t) = 0$, i.e. $u_1(t) = \frac{1}{2}, u_2(t) = \frac{1}{2}$ for $t \in]\frac{1}{2}, 1]$. It follows that the infimum is equal to

$$p^* = \int_0^{1/2} \left(\frac{1}{2} - t\right)^2 dt = \frac{1}{24} \approx 4.1667 \cdot 10^{-2}.$$

Because of chattering, the infimum in problem (1) is not attained by an admissible switching sequence. It is however attained in the convexified problem (4).

The optimal moments can be obtained analytically

$$y_{1,\alpha} = \int_0^{\frac{1}{2}} t^\alpha dt + \frac{1}{2} \int_{\frac{1}{2}}^1 t^\alpha dt = \frac{2 + 2^{-\alpha}}{4 + 4\alpha},$$

$$y_{2,\alpha} = \frac{1}{2} \int_{\frac{1}{2}}^1 t^\alpha dt = \frac{2 - 2^{-\alpha}}{4 + 4\alpha}$$

and they can be compared with the following moment vectors obtained numerically at the 7th LMI relaxation:

$$\begin{aligned} \text{computed } y_1 &= (0.74996 \ 0.31246 \ 0.18746 \ 0.13277 \ 0.10308 \dots), \\ \text{exact } y_1 &= (0.75000 \ 0.31250 \ 0.18750 \ 0.13281 \ 0.10313 \dots), \\ \text{computed } y_2 &= (0.25004 \ 0.18754 \ 0.14588 \ 0.11723 \ 0.096919 \dots), \\ \text{exact } y_2 &= (0.25000 \ 0.18750 \ 0.14583 \ 0.11719 \ 0.096875 \dots). \end{aligned}$$

We observe that the computed moments closely match the exact optimal moments, so that the approximate control law extracted from the computed moments will be almost optimal.

6.2 Double integrator

We revisit the double integrator example with state constraint studied in [27], formulated as the following optimal switching problem:

$$\begin{aligned} p^* &= \inf T \\ \text{s.t. } & \dot{x}(t) = f_{\sigma(t)}(x(t)), \\ & x(0) = [1, 1], \quad x(T) = [0, 0] \\ & x_2(t) \geq -1, \quad \forall t \in [0, T] \end{aligned}$$

where the infimum is w.r.t. to a switching sequence $\sigma : [0, T] \mapsto \{1, 2\}$ with free terminal time $T \geq 0$ and affine dynamics

$$f_1 := \begin{bmatrix} x_2 \\ -1 \end{bmatrix}, \quad f_2 := \begin{bmatrix} x_2 \\ 1 \end{bmatrix}.$$

We know from [27] that the optimal sequence consists of starting with mode 1, i.e. $u_1(t) = 1$, $u_2(t) = 0$ for $t \in [0, 2]$, then chattering with equal proportion between mode 1 and 2, i.e. $u_1(t) = u_2(t) = \frac{1}{2}$ for $t \in [2, \frac{5}{2}]$ and then eventually driving the state to the origin with mode 2, i.e. $u_1(t) = 0$, $u_2(t) = 1$ for $t \in [\frac{5}{2}, \frac{7}{2}]$. Here too the infimum $p^* = \frac{7}{2}$ is not attained for problem (1), whereas it is attained with the above controls for problem (4).

In Table 1 we report the lower bounds p_d^* on the optimal value p^* obtained by solving LMI relaxations (41) of increasing orders d , rounded to 5 significant digits. We also indicate the number of variables \bar{n} (i.e. total number of moments) of each LMI problem, as well as the zeroth order moment of each occupation measure (recall that these are approximations of the time spent on each mode). We observe that the values of the lower bounds and the masses stabilize quickly to the optimal values $p^* = \frac{7}{2}$, $y_{1,0} = \frac{5}{2}$, $y_{2,0} = \frac{5}{4}$.

d	p_d^*	\bar{n}	$y_{1,0}$	$y_{2,0}$
1	2.5000	30	1.7500	0.75000
2	3.2015	105	2.1008	1.1008
3	3.4876	252	2.2438	1.2438
4	3.4967	495	2.2484	1.2484
5	3.4988	858	2.2494	1.2494
6	3.4993	1365	2.2496	1.2497
7	3.4996	2040	2.2498	1.2498

Table 2: Lower bounds p_d^* on the optimal value p^* obtained by solving LMI relaxations of increasing orders d ; \bar{n} is the number of variables in the LMI problem; $y_{j,0}$ is the approximate time spent on each mode $j = 1, 2$.

The optimal switching sequence, which corresponds here to control measures $\omega_k(dt)$ with piecewise constant densities, is obtained numerically as explained in §4, by considering the moments of the (weak) derivative of control measures.

Finally, Fig. 1 shows a logarithmic plot of the computational times of the unstructured generic LMI relaxations of [27] versus their structured modal counterpart, for relaxation orders 1 to 7. The computational gains induced by using modal occupation measures follow the expected exponential improvement, with an exponent of about 1.7, better than the $\frac{4}{3}$ predicted by the asymptotic analysis of §3.4.

Figure 1: Logarithmic plot of computational times required by generic LMI relaxations [27] (vertical axis) versus modal LMI relaxations (horizontal axis), for relaxation order $d = 1, \dots, 7$.

6.3 Switched linear dynamics

Consider the optimal control problem (1):

$$\begin{aligned} p^* &= \inf \int_0^\infty \|x(t)\|_2^2 dt \\ \text{s.t. } &\dot{x}(t) = A_{\sigma(t)}x(t), \\ &x(0) = [0, -1] \end{aligned}$$

where the infimum is w.r.t. to a switching sequence $\sigma : [0, \infty) \mapsto \{1, 2\}$ and

$$A_1 := \begin{bmatrix} -1 & 2 \\ 1 & -3 \end{bmatrix}, \quad A_2 := \begin{bmatrix} -2 & -2 \\ 1 & -1 \end{bmatrix}.$$

Since our framework cannot directly accommodate infinite-horizon problems, we introduce a terminal condition $\|x(T)\|_2^2 \leq 10^{-6}$ so that terminal time T is finite. That is, the switching sequence should drive the state in a small ball centered at the origin.

d	p_d^*	\bar{n}	$y_{1,0}$	$y_{2,0}$
1	0.24294	30	1.4252	1.4489
2	0.24340	105	2.0639	1.9237
3	0.24347	252	1.9639	1.8922
4	0.24347	495	1.9537	1.8904
5	0.24347	858	1.9572	1.8872
6	0.24347	1365	1.9677	1.8940
7	0.24347	2040	1.9669	1.8928

Table 3: Lower bounds p_d^* on the optimal value p^* obtained by solving LMI relaxations of increasing orders d ; \bar{n} is the number of variables in the LMI problem; $y_{j,0}$ is the approximate time spent on each mode $j = 1, 2$.

In Table 3, we report the lower bounds p_d^* on the optimal value p^* obtained by solving LMI relaxations (41) of increasing orders d , rounded to 5 significant digits. We also indicate the number of variables \bar{n} (i.e. total number of moments) of each LMI problem, as well as the zeroth order moment of each occupation measure (recall that these are approximations of the time spent on each mode by (26)). We observe that the values of the lower bounds stabilize quickly.

In Fig. 2, we plot an almost optimal trajectory inferred from the moments of the occupation measure via the method of §4, for an LMI relaxation of order $d = 8$. The trajectory consists in starting from $x = (-1, 0)$ with mode 1 during 0.065 time units, and then chattering between mode 1 and mode 2 with respective proportions 49.3/50.7 until x reaches the neighborhood of the origin $\|x(T)\|_2^2 \leq 10^{-6}$ for $T = 3.84$. This trajectory is suboptimal, as it yields a cost of 0.24351, slightly bigger than the guaranteed lower bound of 0.24347 on the best achievable cost obtained by the LMI relaxation. It follows that this trajectory is very close to optimality. For comparison with available suboptimal solutions, using [20, Theorem 1], the so-called min switching strategy yields with piecewise quadratic Lyapunov functions a suboptimal trajectory with a cost of 0.24948.

Figure 2: Suboptimal trajectory starting at source point $x = (-1, 0)$ with mode 1, then chattering between modes 1 and 2 to reach the target, a neighborhood of the origin.

6.4 Turnpike control

Consider the following problem excerpted from [11, §22.2]:

$$\begin{aligned}
 p^* &= \inf_{u(t)} \int_0^2 (x(t) + u(t)) dt \\
 \text{s.t.} \quad &\dot{x}(t) = x(t) + 1 - x(t)u(t), \\
 &x(0) = 0, \quad x(t) \in [-5, 5], \\
 &u(t) \in U = [0, 3].
 \end{aligned}$$

The optimal solution, a turnpike control policy, is given by:

$$u^*(t) = \begin{cases} 0, & t \in [0, \log 2], \\ 2, & t \in [\log 2, 2 - \log 2], \\ 0, & t \in [2 - \log 2, 2]. \end{cases}$$

We now tackle this problem using the method outlined in this paper. The problem is affine in the control, and as the control set is a simple interval, the problem can be recast

as

$$\begin{aligned}
 p^* &= \inf_{\sigma(t)} \int_0^2 l_{\sigma(t)}(x(t)) dt \\
 \text{s.t.} \quad &\dot{x}(t) = f_{\sigma(t)}(x(t)), \\
 &x(0) = 0, \quad x(t) \in [-5, 5]
 \end{aligned}$$

where the infimum is now w.r.t. to a switching sequence $\sigma : [0, T] \mapsto \{1, 2\}$ with dynamics and costs

$$\begin{aligned}
 f_1 &= x + 1, & f_2 &= -2x + 1, \\
 l_1 &= x, & l_2 &= x + 3.
 \end{aligned}$$

That is, the mode $\sigma = 1$, resp. $\sigma = 2$ is associated with driving the system with the control $u(t) = 0$, resp. $u(t) = 3$.

Table 4 shows the numerical results obtained by applying our LMI approach. Compare this with the optimal cost of 3.4548 and the optimal time spent on each mode, resp. 1.5909 and 0.4091.

d	p_d^*	\bar{n}	$y_{1,0}$	$y_{2,0}$
1	-8.6084	18	1.6296	0.3704
2	-1.7507	45	1.5229	0.4771
3	3.3444	84	1.5713	0.4287
4	3.4492	135	1.5885	0.4115
5	3.4538	198	1.5904	0.4096
6	3.4543	273	1.5906	0.4094
7	3.4544	360	1.5907	0.4093

Table 4: Lower bounds p_d^* on the optimal value p^* obtained by solving LMI relaxations of increasing orders d ; \bar{n} is the number of variables in the LMI problem; $y_{j,0}$ is the approximate time spent on each mode $j = 1, 2$.
