A Subsampling Line-Search Method with Second-Order Results

Abstract

In many contemporary optimization problems, such as hyperparameter tuning for deep learning architectures, it is computationally challenging or even infeasible to evaluate an entire function or its derivatives. This necessitates the use of stochastic algorithms that sample problem data, which can jeopardize the guarantees classically obtained through globalization techniques via a trust region or a line search. Using subsampled function values is particularly challenging for the latter strategy, that relies upon multiple evaluations. On top of that all, there has been an increasing interest for nonconvex formulations of data-related problems. For such instances, one aims at developing methods that converge to second-order stationary points, which is particularly delicate to ensure when one only accesses subsampled approximations of the objective and its derivatives.

This paper contributes to this rapidly expanding field by presenting a stochastic algorithm based on negative curvature and Newton-type directions, computed for a subsampling model of the objective. A line-search technique is used to enforce suitable decrease for this model, and for a sufficiently large sample, a similar amount of reduction holds for the true objective. By using probabilistic reasoning, we can then obtain worst-case complexity guarantees for our framework, leading us to discuss appropriate notions of stationarity in a subsampling context. Our analysis, which we illustrate through real data experiments, encompasses the full sampled regime as a special case: it thus provides an insightful generalization of second-order line-search paradigms to subsampled settings.

Keywords: Nonconvex optimization, finite-sum problems, subsampling methods, negative curvature, worst-case complexity.

1 Introduction

In this paper, we aim to solve

$$\min_{x \in \mathbb{R}^n} f(x) := \frac{1}{N} \sum_{i=1}^{N} f_i(x),$$

where the objective function $f$ is not necessarily convex and the components $f_i$ are assumed to be twice-continuously differentiable on $\mathbb{R}^n$. We are interested in the cases in which the number of components $N \geq 1$ is extremely large: for this reason, we will assume that it is computationally infeasible to evaluate the entire function, its gradient or its Hessian.

To overcome this issue, we consider the use of subsampling techniques to compute stochastic estimates of the objective function, its gradient and its Hessian. Given a random set $S$ sampled from $\{1, \ldots, N\}$ and a point $x \in \mathbb{R}^n$, we will use

$$m(x; S) := \frac{1}{|S|} \sum_{i \in S} f_i(x), \quad g(x; S) := \frac{1}{|S|} \sum_{i \in S} \nabla f_i(x), \quad H(x; S) := \frac{1}{|S|} \sum_{i \in S} \nabla^2 f_i(x),$$

(2)

to estimate the quantities $f(x), \nabla f(x), \nabla^2 f(x)$, respectively, where $|S|$ denotes the cardinal of the sampling set $S$. We are interested in iterative minimization processes that use a different, randomly selected sampling set $S$ at every iteration.

The standard subsampling optimization procedure is the stochastic gradient descent (SGD) method, wherein the gradient is estimated by a subsampled (also called mini-batch) gradient and a step is taken in the negative of this direction. This is still the standard approach in many applications, including large-scale machine learning problems, particularly those arising from the training of deep neural net architectures [8]. However, SGD is known to be sensitive to nonconvexity, particularly in the context of training deep neural nets. It has indeed been observed that the optimization landscape for the associated (nonconvex) objective exhibits a significant number of saddle points, around which the flatness of the function tended to slow down the convergence of SGD [15]. Note that first-order methods almost never converge to saddle points [22], but are generally slowed down around the neighborhood of such points. One possible way to tackle this issue is to incorporate second-order information so as to guarantee that saddle points can be escaped from at a favorable rate. Various algorithms that provide such guarantees while only requiring gradient or Hessian-vector products have also been proposed, see for instance [1, 2, 23, 32]. Under certain accuracy conditions, which can be satisfied with arbitrarily high probability by controlling the size of the sample, these methods produce a sequence of iterates that converge to a local minimizer at a certain rate. Alternatively, one can extract second-order information and escape saddle points using accelerated gradient techniques in the stochastic setting [30]. The results are also in high probability, with a priori tuned step-sizes. Noise can be used to approximate second-order information as well [32]. Recent proposals [31, 33] derive high probability convergence results with second-order steps (e.g., Newton steps) based on sampled derivatives, by means of trust-region and cubic regularization frameworks.

Subsampling can be viewed as a particular case of stochastic optimization where the underlying distribution takes values within a discrete set. In the general stochastic optimization setting, a variety of algorithms have been extended to handle access to (sub)sampled derivatives, and possibly function values: of particular interest to us are the algorithms endowed with complexity guarantees. When the function values are assumed to be exactly available or are not used, one can employ strategies based on line search [11], cubic regularization [11, 19] or trust-region paradigms [14, 18] to compute a step of suitable length. Many algorithms building on SGD require the tuning of the step size parameter (also called learning rate), which can be cumbersome without knowledge of the Lipschitz constant. On the contrary, methods that are based on a globalization technique (line search, trust region, quadratic or cubic regularization) can control the size of the step in an adaptive way, and are thus less sensitive to parameter tuning.
In spite of their attractive properties with respect to the step size, globalized techniques are challenging to extend to the context of inexact function values. Indeed, these methods traditionally accept new iterates only if they produce a sufficient reduction of the objective value. Still, inexact variants of these schemes have been a recent topic of interest in the literature. In the context of stochastic optimization, several algorithms that explicitly deal with computing stochastic estimates of the function values, typically of trust-region type [6, 13, 21], have been proposed. In the specific case of least-squares problems, both approaches (exact and inexact function values) have been incorporated within a Levenberg-Marquardt framework [5, 4]. The use of stochastic function estimates in a line-search framework (a process that heavily relies on evaluating the function at tentative points) has also been the subject of very recent investigation. A study based on proprietary data [20] considered an inexact Newton and negative curvature procedure using each iteration’s chosen mini-batch as the source of function evaluation sample in the line search. A more mature approach for line search was presented in [24], where extensive experiments matching performance to pre-tuned SGD were presented. An innovating technique based on a backtracking procedure for steps generated by a limited memory BFGS method for nonconvex problems using first order information was recently proposed in [7], and first-order convergence results were derived. Finally, during the final stages of preparation of this manuscript, a report presenting a stochastic line-search method was released [25]. Similarly to our scheme, this algorithm computes stochastic estimates for function and gradient values, which are then used within a line-search algorithm. However, the two methods differ in their inspiration and results: we provide more details about these differences in the next paragraph, and throughout the paper when relevant.

In this paper, we propose a line-search scheme with second-order guarantees based on sub-sampling function and derivatives. Our method uses these subsampled values to compute Newton-type and negative curvature steps. Although our framework bears similarities with the approach of [25], the two algorithms are equipped with different analyzes, each based on its own argument from probability theory. The method of [25] is designed with first-order guarantees in mind (in particular, the use of negative curvature is not explored), and its complexity results are particularized to the nonconvex, convex and strongly convex cases; our work presents a line-search method that is dedicated to the nonconvex setting, and to the derivation of second-order results. As such, we are able to show a rate of convergence to points satisfying approximate second-order optimality conditions, in expectation. By contrast, earlier work on second-order guarantees for subsampling methods often focused on complexity bounds holding with a high probability (of accurate samples being taken at each iteration), disallowing poor outlier estimates of the problem function. We believe that our results form a complementary and interesting addition to the state of the art literature on stochastic optimization methods.

We organize this paper as follows. In Section 2, we describe our proposed approach based on line-search techniques. In Section 3, we derive bounds on the amount of expected decrease that can be achieved at each iteration by our proposed approach. Section 4 gives the global convergence rate of our method under appropriate assumptions, followed by a discussion about the required properties and their satisfaction in practice. Numerical illustrations are provided in Section 5. A discussion of conclusions and future research is given in Section 6.

Throughout the paper, \( \| \cdot \| \) denotes the Euclidean norm. A vector \( v \in \mathbb{R}^n \) will be called a unit vector if \( \| v \| = 1 \).
2 Subsampling line-search method

This section presents a line-search algorithm for solving the unconstrained optimization problem (1). This framework is based upon the exact version of the method proposed by Royer and Wright [29], but differs in several ways. Unlike [29], we do not consider the use of gradient-based steps. Although those could be added to our method without affecting the complexity guarantees, our purpose here is to advocate for the use of Newton and negative curvature directions; in addition, the upcoming analysis will be simplified with only three different forms of direction to consider (as opposed to five for the algorithm of [29]). As we will see in the next section, our analysis generalizes part of that of [29] to the case of subsampled functions and derivatives.

A detailed description of the proposed scheme is given in Algorithm 1. At each iteration \( k \), our method computes a random sampling set \( S_k \), and the associated model \( m_k(\cdot) := m(\cdot; S_k) \). Based on \( g_k := g(x_k; S_k) \) and \( H_k := H(x_k; S_k) \), a search direction \( d_k \) is computed. The rule for choosing the form of the direction is slightly different from [29], in that it directly compares the minimum Hessian eigenvalue and the gradient norm. As the results of Section 4 will show, both rules lead to similar complexity guarantees in the fully sampled case.

Once the search direction has been determined, a backtracking line-search strategy is then applied to determine a suitable step size \( \alpha_k \) that decreases the model by a sufficient amount (see condition (7)). This condition is instrumental in obtaining good complexity properties.

Two comments about the description of Algorithm 1 are in order. First, we observe that the method as stated is not equipped with a stopping criterion. Apart from budget considerations, one might be tempted to stop the method when the derivatives are suggesting that it is a second-order stationary point. However, since we only have access to subsampled versions of those derivatives, it is possible that we have not reached a stationary point for the true function. As we will establish later in the paper, one needs to take into account the accuracy of the model, and it might take several iterations to guarantee that we are indeed at a stationary point. We thus defer the proper discussion on stopping criteria and stationarity to Section 4.

Our second remark relates to the computation of a step. When the subsampled gradient \( g_k \) is zero and the subsampled matrix \( H_k \) is positive definite, we cannot compute a descent step using first or second-order information, as the current iterate is second-order stationary for the subsampled model. In that situation, and for the reasons mentioned above, we do not stop our method, but rather take a zero step and move to a new iteration and a new sample set. As we will show in Section 4, after a certain number of such iterations, one can guarantee that a stationary point has been reached, with high probability.

3 Expected decrease guarantees with subsampling

In this section, we derive bounds on the amount of expected decrease at each iteration. In doing so, we separate the cases of good and bad approximations. In the case of good approximations, we are able to guarantee decrease in the objective for every step taken in Algorithm 1. By controlling the sample size, one can adjust the probability of having a sufficiently good model, so that the guaranteed decrease for good approximations will compensate a possible increase for bad approximations on average.
Algorithm 1: A Line-search Algorithm based on Subsampling (ALAS).

Initialization: Choose $x_0 \in \mathbb{R}^n$, $\theta \in (0, 1)$, $\eta > 0$, $\epsilon > 0$.

for $k = 0, 1, \ldots$ do

1. Draw a random sample set $S_k \subset \{1, \ldots, N\}$, and compute the associated quantities
   $g_k := g(x_k; S_k)$, $H_k := H(x_k; S_k)$. Form the model:
   \[ m_k(x + s) := m(x + s; S_k). \]  
   \hspace{1cm} (3)

2. Compute $\lambda_k$ as the minimum eigenvalue of the Hessian estimate $H_k$.
   If $\lambda_k \geq 0$ and $\|g_k\| = 0$ set $\alpha_k = 0$, $d_k = 0$ and go to Step 7.

3. If $\lambda_k < -\|g_k\|^{1/2}$, compute a negative eigenvector $v_k$ such that
   $H_k v_k = \lambda_k v_k$, $\|v_k\| = -\lambda_k$, $v_k \top g_k \leq 0$,
   \hspace{1cm} (4)
   set $d_k = v_k$ and go to the line-search step.

4. If $\lambda_k > \|g_k\|^{1/2}$, compute a Newton direction $d_k$ solution of
   \[ H_k d_k = -g_k, \]  
   \hspace{1cm} (5)
   go to the line-search step.

5. If $d_k$ has not yet been chosen, compute it as a regularized Newton direction, solution of
   \[ \left( H_k + (\|g_k\|^{1/2} + \epsilon^{1/2})I \right) d_k = -g_k, \]  
   \hspace{1cm} (6)
   and go to the line-search step.

6. Line-search step Compute the minimum index $j_k$ such that the step length
   $\alpha_k := \theta^{j_k}$ satisfies the decrease condition:
   $m_k(x_k + \alpha_k d_k) - m_k(x_k) \leq -\frac{\eta}{6} \alpha_k^3 \|d_k\|^3$.
   \hspace{1cm} (7)

7. Set $x_{k+1} = x_k + \alpha_k d_k$ and $k = k + 1$.

end
3.1 Preliminary assumptions and definitions

Throughout the paper, we will study Algorithm 1 under the following assumptions.

**Assumption 3.1** The function $f$ is bounded below by $f_{\text{low}} \in \mathbb{R}$.

**Assumption 3.2** The functions $f_i$ are twice continuously differentiable with Lipschitz continuous gradients and Hessians, of respective Lipschitz constants $L_i$ and $L_{H,i}$.

A consequence of Assumption 3.2 is that $f$ is twice continuously differentiable with Lipschitz continuous first and second-order derivatives. This property also holds for $m(\cdot; S)$, regardless of the value of $S$ (we say that the property holds for all realizations of $S$). In what follows, we will always consider that $m(\cdot; S)$ and $f$ have $L$-Lipschitz continuous gradients and $L_H$-Lipschitz continuous Hessians, where

$$L := \max_i L_i, \quad L_H := \max_i L_{H,i}.$$  

**Assumption 3.3** For any realization of the algorithm, the iterates are contained in a compact set.

By Assumption 3.3, for the sequence of iterates $\{x_k\}$ generated by Algorithm 1, there exists a finite positive number $U_g$ such that

$$U_g \geq \max_k \max_{i=1,\ldots,N} \|\nabla f_i(x_k)\|.$$  

The constant $U_g$ can thus be used as an upper bound of the gradient of $f$ or on the gradient of any realization of the model $m(\cdot; \mathcal{S})$. Thanks to Assumption 3.3, we thus know that $U_g < \infty$.

Finally, in what follows, for every iteration $k$, we let

$$\pi_k := \frac{|S_k|}{N} \quad \text{and} \quad i_k \in \arg\max_{i \in S_k} \left\{ \alpha_k \nabla f_i(x_k)^\top d_k + \frac{L}{2} \alpha_k^2 \|d_k\|^2 \right\}.$$  

The index $i_k$ will help in identifying the worst-case behavior induced by a step taken over a bad approximation.

Since the sample sets in Algorithm 1 are drawn at random, the subsampling process introduces randomness in an iterative fashion at every iteration. As a result, Algorithm 1 results in a stochastic process $\{x_k, d_k, \alpha_k, g_k, H_k, m_k(x_k), m_k(x_k + \alpha_k d_k)\}$. To keep the notation of the paper simpler, we will use these notations for the random variables and their realizations. Most of our analysis will be concerned with random variables, but we will explicitly mention that realizations are considered when needed.

Our goal is to show that under certain conditions on the sequences $\{g_k\}$, $\{H_k\}$, $\{m_k(x_k)\}$, $\{m_k(x_k + \alpha_k d_k)\}$ the resulting stochastic process has desirable convergence properties with probability one.

Inspired by a number of definitions in the model-based literature for stochastic or subsampled methods [3, 13, 21, 23], we introduce a notion of sufficient accuracy for our model function and its derivatives.

**Definition 3.1** Given a realization of Algorithm 1 and an iteration index $k$, the model $m_k : \mathbb{R}^n \mapsto \mathbb{R}$ is said to be $(\delta_f, \delta_g, \delta_H)$-accurate for $(f, x_k, \alpha_k, d_k)$ when

$$|f(x_k) - m_k(x_k)| \leq \delta_f \quad \text{and} \quad |f(x_k + \alpha_k d_k) - m_k(x_k + \alpha_k d_k)| \leq \delta_f,$$  

where
\[
\| \nabla f(x_k) - g_k \| \leq \delta_g, \quad (9)
\]
as well as
\[
\| \nabla^2 f(x_k) - H_k \| \leq \delta_H, \quad (10)
\]
where \( g_k := \nabla m_k(x_k) \), \( H_k := \nabla^2 m_k(x_k) \) and \( \delta_f, \delta_g, \delta_H \) are nonnegative constants.

Condition (8) will be instrumental in establishing decrease guarantees for our method, while conditions (9) and (10) will play a key role in defining proper notions of stationarity (see Section 4). Since we are operating with a sequence of random samples and models, we need a probabilistic equivalent of Definition 3.1, which is given below.

**Definition 3.2** Let \( p \in (0, 1] \), \( \delta \geq 0 \), \( \delta_g \geq 0 \) and \( \delta_H \geq 0 \). A sequence of functions \( \{m_k\}_k \) is called \( p \)-probabilistically \((\delta_f, \delta_g, \delta_H)\)-accurate for Algorithm 1 if the events
\[
I_k := \{m_k \text{ is } (\delta_f, \delta_g, \delta_H)\text{-accurate with respect to } (f, x_k, \alpha_k, d_k)\}
\]
satisfy
\[
p_k := P(I_k | \mathcal{F}_{k-1}) \geq p,
\]
where \( \mathcal{F}_{k-1} \) is the \( \sigma \)-algebra generated by the sample sets \( S_0, S_1, \ldots, S_{k-1} \), and we define
\[
P(I_0 | \mathcal{F}_{-1}) := P(I_0).
\]

Observe that if we sample the full data at every iteration (that is, \( S_k = \{1, \ldots, N\} \) for all \( k \)), the resulting model sequence satisfies the above definition for any \( p \in [0, 1] \) and any positive values \( \delta_f, \delta_g, \delta_H \). In fact, the properties above could be considered as obtained by the random sampling sets rather than the models; however, to stay consistent with the existing literature, we will talk about accuracy of the models.

In the rest of the paper, we assume that the estimate functions of the problem are \( p \)-probabilistically \((\delta_f, \delta_g, \delta_H)\)-accurate, for some given \( p \in (0, 1] \).

**Assumption 3.4** The sequence \( \{m_k\}_k \) produced by Algorithm 1 is \( p \)-probabilistically \( \delta \)-accurate, with \( \delta := (\delta_f, \delta_g, \delta_H) \) and \( p \in (0, 1] \).

### 3.2 A general expected decrease result

In this section, we study the guarantees that can be obtained (in expectation) for the various types of direction considered by our method. By doing so, we identify the necessary requirements on our sampling procedure, as well as on our accuracy threshold for the model values.

Before studying each direction type individually, we provide a generic guarantee on the expected decrease at every iteration through the result of Theorem 3.1.

**Theorem 3.1** Let Assumptions 3.1, 3.2 and 3.4 hold. At a given iteration \( k \), suppose that \( \alpha_k \|d_k\| \geq \varepsilon \) for some \( \varepsilon \in (0, 1) \). If \( \delta_f \) is such that
\[
\delta_f \leq \frac{\eta}{24\varepsilon^3}, \quad (11)
\]
and the sample size satisfies
\[
\pi_k \geq \varrho_k(\varepsilon) := \frac{\|\nabla f_k(x_k)\| + \frac{L_{ik}}{2}\varepsilon}{\|\nabla f_k(x_k)\| + \frac{L_{ik}}{2}\varepsilon + \frac{\eta}{24\varepsilon^2}}, \quad (12)
\]

7
Then,

$$
\mathbb{E} [f(x_k + \alpha_k d_k) - f(x_k) \mid \mathcal{F}_{k-1}] \leq -\pi_k p_k \frac{\eta}{12} \alpha_k^3 \|d_k\|^3 \leq -g_k(\varepsilon) p \frac{\eta}{12} \alpha_k^3 \|d_k\|^3. \quad (13)
$$

**Proof.** By definition, one has that:

$$
\mathbb{E} [f(x_k + \alpha_k d_k) - f(x_k) \mid \mathcal{F}_{k-1}] = \mathbb{E} [f(x_k + \alpha_k d_k) - f(x_k) \mid \mathcal{F}_{k-1}, I_k] p_k + \mathbb{E} [f(x_{k+1}) - f(x_k) \mid \mathcal{F}_{k-1}, I_k] (1 - p_k),
$$

in which $I_k$ represent the events where the estimates $(m_k, g_k, H_k)$ are not $\delta$-accurate.

We can bound each term separately, starting with the first one corresponding to the event of accurate estimates. In that case, since the event $I_k$ happens, we have

$$
f(x_k + \alpha_k d_k) - f(x_k) = f(x_k + \alpha_k d_k) - m_k(x_k + \alpha_k d_k) + m_k(x_k + \alpha_k d_k) - m_k(x_k) + m_k(x_k) - f(x_k)
\leq 2\delta + m_k(x_k + \alpha_k d_k) - m_k(x_k)
\leq \frac{\eta}{12} \varepsilon^3 - \frac{\eta}{6} \alpha_k^3 \|d_k\|^3
\leq \frac{\eta}{12} \alpha_k^3 \|d_k\|^3 - \frac{\eta}{6} \alpha_k^3 \|d_k\|^3 = -\pi_k \frac{\eta}{12} \alpha_k^3 \|d_k\|^3,
$$

where we used the bound (11) and the fact that $\alpha_k \|d_k\| \geq \varepsilon$.

We now turn to the second case, where we exploit the following decomposition of $f(x_k + \alpha_k d_k) - f(x_k)$:

$$
f(x_k + \alpha_k d_k) - f(x_k) = \pi_k (m_k(x_k + \alpha_k d_k) - m_k(x_k)) + (1 - \pi_k) (f_{S_k^c}(x_k + \alpha_k d_k) - f_{S_k^c}(x_k)),
$$

with $f_{S_k} = \frac{1}{N - |S_k|} \sum_{i \notin S_k} f_i$. Hence,

$$
f(x_k + \alpha_k d_k) - f(x_k)
\leq -\pi_k \frac{\eta}{6} \alpha_k^3 \|d_k\|^3 + (1 - \pi_k) \frac{1}{N - |S_k|} \sum_{i \notin S_k} \left\{ \alpha_k \nabla f_i(x_k)^\top d_k + \frac{L_i}{2} \alpha_k^2 \|d_k\|^2 \right\}
\leq -\pi_k \frac{\eta}{6} \alpha_k^3 \|d_k\|^3 + (1 - \pi_k) \max_{i \notin S_k} \left\{ \alpha_k \nabla f_i(x_k)^\top d_k + \frac{L_i}{2} \alpha_k^2 \|d_k\|^2 \right\}
\leq -\pi_k \frac{\eta}{12} \alpha_k^3 \|d_k\|^3 + (1 - \pi_k) \left\{ \alpha_k \|\nabla f_{i_k}(x_k)\| \|d_k\| + \frac{L_{i_k}}{2} \alpha_k^2 \|d_k\|^2 \right\},
$$

where $i_k \in \arg\max_{i \notin S_k} \left\{ \alpha_k \nabla f_i(x_k)^\top d_k + \frac{L_i}{2} \alpha_k^2 \|d_k\|^2 \right\}$ and we used the Lipschitz continuity assumption on the functions $f_i$'s.

By combining (14) and (15), we obtain:

$$
\mathbb{E} [f(x_k + \alpha_k d_k) - f(x_k) \mid \mathcal{F}_{k-1}]
\leq -\pi_k p_k \frac{\eta}{12} \alpha_k^3 \|d_k\|^3 - \pi_k (1 - p_k) \frac{\eta}{12} \alpha_k^3 \|d_k\|^3 + (1 - \pi_k) \left\{ \alpha_k \|\nabla f_{i_k}(x_k)\| \|d_k\| + \frac{L_{i_k}}{2} \alpha_k^2 \|d_k\|^2 \right\}
\leq -\pi_k \frac{\eta}{12} \alpha_k^3 \|d_k\|^3 + (1 - \pi_k) (1 - p_k) \left\{ \alpha_k \|\nabla f_{i_k}(x_k)\| \|d_k\| + \frac{L_{i_k}}{2} \alpha_k^2 \|d_k\|^2 \right\}
= \alpha_k \|d_k\| \left[-\pi_k \frac{\eta}{12} \alpha_k^3 \|d_k\|^2 + (1 - \pi_k) (1 - p_k) \left\{ \|\nabla f_{i_k}(x_k)\| + \frac{L_{i_k}}{2} \alpha_k \|d_k\| \right\} \right].
$$
Using the above equation, we have that (13) holds provided
\[
- \pi_k \eta \frac{\alpha_k^2}{2} \|d_k\|^2 + (1 - \pi_k) (1 - p_k) \left\{ \|\nabla f_{i_k}(x_k)\| + \frac{L_{i_k}}{2} \alpha_k \|d_k\| \right\} \leq - \pi_k p_k \eta \frac{\alpha_k^2}{2} \|d_k\|^2
\]
\[
\Leftrightarrow - \pi_k (1 - p_k) \left\{ \|\nabla f_{i_k}(x_k)\| + \frac{L_{i_k}}{2} \alpha_k \|d_k\| \right\} \leq 0.
\]

If \( p_k = 1 \), this is trivially true. Otherwise, by rearranging the terms, we observe that the inequality holds provided
\[
\pi_k \geq \frac{\|\nabla f_{i_k}(x_k)\| + \frac{L_{i_k}}{2} \alpha_k \|d_k\|}{\|\nabla f_{i_k}(x_k)\| + \frac{L_{i_k}}{2} \alpha_k \|d_k\| + \eta \frac{\alpha_k^2}{2} \|d_k\|^2} = q_k(\alpha_k \|d_k\|),
\]
and this is implied by \( \pi_k \geq q_k(\varepsilon) \geq q_k(\alpha_k \|d_k\|) \).

Note that conditions (11) and (12) are always satisfied when the whole data is sampled regardless of the value of \( p \) or \( \varepsilon \) (since \( \pi_k = 1 \), one can choose \( \delta_f = 0 \)). Note also that by setting \( p = \pi_k = 1 \), we recover the deterministic result derived in [29] up to a constant factor\(^1\).

**Remark 3.1** In the line-search step of Algorithm 1, we impose a cubic decrease on the estimated objective function (see condition (7)). This is a crucial ingredient for deriving an optimal complexity result. A quadratic decrease of the form
\[
m_k(x_k + \alpha_k d_k) - m_k(x_k) \leq -\eta \frac{\alpha_k^2}{2} \|d_k\|^2.
\]
(16)
can be also used instead of (7) in the line-search step of Algorithm 1. This would yield a suboptimal complexity result, however, for practical implementation, one may prefer the use of a quadratic decrease during the application of Algorithm 1.

When a quadratic decrease of the form (16) is used instead, then, by the same methodology of the proof of Theorem 3.1, the expected decrease on the objective function will be of the form
\[
\mathbb{E}[f(x_k + \alpha_k d_k) - f(x_k) \mid \mathcal{F}_{k-1}] \leq - \pi_k p_k \frac{\eta}{4} \alpha_k^2 \|d_k\|^2,
\]
(17)
provided the sample fraction satisfies
\[
\pi_k \geq \frac{\|\nabla f_{i_k}(x_k)\| + \frac{L_{i_k}}{2} \varepsilon}{\|\nabla f_{i_k}(x_k)\| + \left( \frac{L_{i_k}}{2} + \frac{\eta}{4} \right) \varepsilon},
\]
where \( \delta_f \leq \frac{\eta}{8} \varepsilon^2 \) and \( \alpha_k \|d_k\| \geq \varepsilon \) for some \( \varepsilon \in (0, 1) \).

### 3.3 Expected decrease lemmas for negative curvature and Newton-type steps

In this section, we apply Theorem 3.1 to our three particular choices for the direction \( d_k \), and derive expected decrease guarantees for each choice. The upcoming results will be based on the guarantees provided on the model decrease; in particular, we will leverage the finite termination

\(^1\)This constant factor of \( \frac{1}{2} \) arises from the overestimation of \( \delta_f \) by a positive constant, while in the deterministic case we have \( \delta_f = 0 \).
properties of the backtracking line-search process that were established in [29]. In our case, those will apply to the model \( m_k \) rather than the true function \( f \).

In what follows, we will make use of the function:

\[ \varrho(t) := \frac{U_g + \frac{L}{2} t}{U_g + \frac{L}{2} t + \frac{\eta}{12} t^2}, \]  

Under Assumptions 3.2 and 3.3, this function is well-defined and decreasing for \( t \in [0, \infty) \). Moreover, one has \( \varrho(t) \geq \varrho_k(t) \) for all \( k \), where \( \varrho_k \) is defined in Theorem 3.1.

Our first result is related to negative curvature steps.

**Lemma 3.1** Let Assumptions 3.1, 3.2, 3.3 and 3.4 hold. At a given iteration \( k \), suppose that the direction \( d_k \) is selected as a subsampled negative curvature direction with \( -\lambda_k > 0 \). If \( \pi_k \geq \varrho(c_{nc}[-\lambda_k]) \), and \( \delta_f \leq \frac{\eta}{24} c_{nc}^3[-\lambda_k]^3 \),

where \( c_{nc} := \frac{3\theta}{L_H + \eta} \), then, the backtracking line search terminates with the step length \( \alpha_k = \theta j_k \), with \( j_k \leq \bar{j}_{nc} + 1 \), where

\[ \bar{j}_{nc} := \lfloor \log_\theta \left( \frac{3}{L_H + \eta} \right) \rfloor + , \]  

and the expected decrease satisfies,

\[ \mathbb{E}[f(x_k + \alpha_k d_k) - f(x_k) | \mathcal{F}_{k-1}] \leq -\pi_k \frac{\eta}{12} c_{nc}^3[-\lambda_k]^3. \]  

**Proof.** By applying the same reasoning than in [29, Proof of Lemma 1] (with the model \( m_k \) playing the role of the objective), the backtracking line search terminates with the step length \( \alpha_k = \theta j_k \), with \( j_k \leq \bar{j}_{nc} + 1 \) and \( \alpha_k \geq \frac{3\theta}{L_H + \eta} \). When \( d_k \) is computed as a negative curvature direction, one has \( \|d_k\| = -\lambda_k \). Hence,

\[ \alpha_k^3 \|d_k\|^3 \geq \frac{27\theta^3}{(L_H + \eta)^3}[-\lambda_k]^3 = c_{nc}^3[-\lambda_k]^3. \]  

The desired result is then given by application of Theorem 3.1 with \( \varepsilon = c_{nc}[-\lambda_k] \).

Note that (21) is an inequality between two conditional expectations that are random variables leaving in \( \mathcal{F}_k \). Indeed, since \( \lambda_k, \pi_k \in \mathcal{F}_{k-1} \), one has

\[ \mathbb{E}\left[-\pi_k \frac{\eta}{12} c_{nc}^3[-\lambda_k]^3 | \mathcal{F}_{k-1}\right] = -\pi_k \frac{\eta}{12} c_{nc}^3[-\lambda_k]^3. \]

A similar observation holds for the results of Lemmas 3.2 and 3.3.

The next lemmas provide expected decrease guarantees when the step is either a subsampled Newton step or a subsampled regularized Newton step. The decrease formulas will involve the norm of the vector:

\[ g_k^+ := g(x_k + \alpha_k d_k; S_k). \]  

The norm of this “next gradient” is a major tool for the derivation of complexity results in Newton-type methods, see for instance [10, 29]. In a subsampled setting, a distinction between \( g_k^+ \) and \( g_{k+1} \) has to be made as those vectors are computed using different sample sets.
Lemma 3.2 Let Assumptions 3.1, 3.2, 3.3 and 3.4 hold. For a given index \( k \), suppose that \( \|g_k\| > 0 \) and that the direction \( d_k \) is a subsampled Newton one. If
\[
\pi_k \geq c_n \|\tilde{g}_k\|^{1/2}, \quad \text{and} \quad \delta_f \leq \frac{\eta}{24} c_n^2 \|\tilde{g}_k\|^{3/2},
\]
where \( \|\tilde{g}_k\| := \min\{\|g_k\|, \|g_k^+\|\} \) and \( c_n := \min\left\{\left[\frac{2}{L_H}\right]^{1/2}, \left[\frac{3\theta}{L_H + \eta}\right]\right\} \). Then, the backtracking line search terminates with step length \( \alpha_k = \theta^{j_k} \), with \( j_k \leq \bar{j}_n + 1 \), where
\[
\bar{j}_n := \left\lfloor \log_\theta \left( \sqrt{\frac{3}{L_H + \eta}} \frac{\|g_k\|^{1/2}}{\sqrt{U_g}} \right) \right\rfloor + 1 = \bar{j}_n + 1,
\]
and the expected decrease satisfies,
\[
\mathbb{E}[f(x_k + \alpha_k d_k) - f(x_k) \mid F_{k-1}] \leq -\pi_k \frac{\eta}{12} c_n^3 \|\tilde{g}_k\|^{3/2}. \tag{25}
\]

**Proof.** From Algorithm 1, we know that if \( d_k \) is chosen as the Newton step we must have \( \lambda_k \geq \|g_k\|^{1/2} \). Using the argument of [29, Proof of Lemma 3] with \( \epsilon_H = \|g_k\|^{1/2} \), the backtracking line search terminates with the step length \( \alpha_k = \theta^{j_k} \), where
\[
j_k \leq \left\lfloor \log_\theta \left( \sqrt{\frac{3}{L + \eta}} \frac{\|g_k\|^{1/2}}{\sqrt{U_g}} \right) \right\rfloor + 1 = \bar{j}_n + 1,
\]
thus the first part of the result holds. If the unit step size is chosen, we have by [29, Relation (23)] that
\[
\alpha_k^3 \|d_k\|^3 = \|d_k\|^3 \geq \left[ \frac{2}{L_H} \right]^{3/2} \|g(x_k + \alpha_k d_k, \mathcal{S}_k)\|^{3/2}. \tag{26}
\]
Consider now the case \( \alpha_k < 1 \). Using [29, Relations (25) and (26), p. 1457], we have:
\[
\|d_k\| \geq \frac{3}{L_H + \eta} \epsilon_H = \frac{3}{L_H + \eta} \|g_k\|^{1/2}
\]
and
\[
\alpha_k \geq \theta \sqrt{\frac{3}{L_H + \eta}} \epsilon_H \|d_k\|^{-1/2} = \theta \sqrt{\frac{3}{L_H + \eta}} \|g_k\|^{1/4} \|d_k\|^{-1/2}.
\]
As a result,
\[
\alpha_k^3 \|d_k\|^3 \geq \theta^3 \left[ \frac{3}{L_H + \eta} \right]^{3/2} \|g_k\|^{3/4} \|d_k\|^{-3/2} \|d_k\|^3
\]
\[
\alpha_k^3 \|d_k\|^3 \geq \left[ \frac{3\theta}{L_H + \eta} \right]^3 \|g_k\|^{3/2}. \tag{27}
\]
Putting (26) and (27) together, we obtained the desired result by application of Theorem 3.1 with
\[
\varepsilon = c_n \min\{\|g_k\|^{1/2}, \|g(x_k + \alpha_k d_k, \mathcal{S}_k)\|^{1/2} \}.
\]

The following lemma gives the expected decrease on the objective function that can be guaranteed when the regularized Newton direction is used.
Lemma 3.3 \textit{Let Assumptions 3.1, 3.2, 3.3 and 3.4 hold. For a given index }$k$\textit{, suppose that }$\|g_k\| > 0$\textit{ and that the direction }$d_k$\textit{ is a subsampled regularized Newton direction. If}

$$\pi_k \geq \varrho \left( c_{rn} \min \left\{ \|\tilde{g}_k\| \epsilon^{-1/2}, \epsilon^{1/2} \right\} \right), \quad \text{and} \quad \delta_f \leq \frac{n}{24} c_{rn} \min \left\{ \|\tilde{g}_k\| \epsilon^{-3/2}, \epsilon^{3/2} \right\}, \quad (28)$$

\textit{where }$\|\tilde{g}_k\| := \min \{\|g_k\|, \|g_k^+\|\}$\textit{ and }$c_n := \min \left\{ \frac{1}{\sqrt{1 + L_H/2}}, \left[ \frac{6\varrho}{\epsilon + L_H} \right] \right\}$\textit{. Then, the backtracking line search terminates with step length }$\alpha_k = \theta^{j_k}$\textit{ with }$j_k \leq \bar{j}_{rn} + 1$, \textit{where}

$$\bar{j}_{rn} := \left\lceil \log_\theta \left( \frac{6\epsilon}{U_g(L_H + \eta)} \right) \right\rceil_+, \quad (29)$$

\textit{and the expected decrease satisfies,}

$$\mathbb{E} [f(x_k + \alpha_k d_k) - f(x_k) | \mathcal{F}_{k-1}] \leq -\pi_k \frac{\eta}{12} c_{rn} \min \left\{ \|\tilde{g}_k\| \epsilon^{-3/2}, \epsilon^{3/2} \right\}. \quad (30)$$

**Proof.** As in the proof of the previous lemma, we apply the theory of [29, Proof of Lemma 4] using }$\epsilon_H = \epsilon^{1/2}$\textit{. We then know that the backtracking line search terminates with the step length }$\alpha_k = \theta^{j_k}$\textit{, with}

$$j_k := \left\lceil \log_\theta \left( \frac{6\epsilon}{U_g(L_H + \eta)} \right) \right\rceil_+ + 1 = \bar{j}_{rn} + 1,$$

\textit{since }$\epsilon_H = \epsilon^{1/2}$\textit{.}

We now distinguish between the cases }$\alpha_k = 1$\textit{ and }$\alpha_k < 1$. \textit{If the unit step size is chosen, we can use }[29, Relations (30) and (31)], \textit{where }$\nabla f(x_k + d_k)$\textit{ and }$\epsilon_H$\textit{ are replaced by }$g_k^+$\textit{ and }$\epsilon^{1/2}$\textit{, respectively. This gives}

$$\alpha_k \|d_k\| = \|d_k\| \geq \frac{1}{1 + \sqrt{1 + L_H/2}} \min \left\{ \|g_k^+\| \epsilon^{-1/2}, \epsilon^{1/2} \right\}. \quad (31)$$

Therefore, if the unit step is accepted, one has (see [29, Equation (31)])

$$\alpha_k \|d_k\| \geq \frac{1}{1 + \sqrt{1 + L_H/2}} \min \left\{ \|g_k^+\| \epsilon^{-1/2}, \epsilon^{1/2} \right\} \geq \frac{1}{1 + \sqrt{1 + L_H/2}} \min \left\{ \|\tilde{g}_k\| \epsilon^{-1/2}, \epsilon^{1/2} \right\}. \quad (30)$$

Considering now the case }$\alpha_k < 1$\textit{ and using [29, (32), p. 1459], we have:

$$\alpha_k \geq \theta \frac{6}{L_H + \eta} \epsilon H \|d_k\|^{-1} = \frac{6\varrho}{L_H + \eta} \epsilon^{1/2} \|d_k\|^{-1},$$

\textit{which leads to}

$$\alpha_k \|d_k\| \geq \frac{6\varrho}{L_H + \eta} \epsilon^{1/2}. \quad (31)$$

12
Putting (30) and (31) together, we obtain

\[ \alpha_k \|d_k\| \geq \min \left\{ \frac{1}{(1 + \sqrt{1 + \frac{LH}{2}})^2}, \frac{6\theta}{LH + \eta} \right\} \min \{\|\tilde{g}_k\|\epsilon^{-1/2}, \epsilon^{1/2}\} \]

\[ = c_{rn} \min \{\|\tilde{g}_k\|\epsilon^{-1/2}, \epsilon^{1/2}\}. \]

Applying Theorem 3.1 with \( \varepsilon = c_{rn} \min \{\|\tilde{g}_k\|\epsilon^{-1/2}, \epsilon^{1/2}\} \) thus gives the desired result.

Thanks to the three lemmas above, we can guarantee that decrease will be achieved in expectation provided the computed model sequence is probabilistically accurate. This is summarized in the following result.

**Proposition 3.1** Let Assumptions 3.1, 3.2, 3.3 and 3.4 hold. Consider an iteration \( k \) such that

\[ \min \{\|g_k\|, \|g_k^+\|\} > \epsilon \quad \text{or} \quad \lambda_k < -\epsilon^{1/2}, \]

where \( g_k, g_k^+ \) and \( \lambda_k \) are defined as in Section 3, and \( \epsilon \) is the tolerance used in Algorithm 1. Then, if

\[ \pi_k \geq \varrho \left( c\epsilon^{1/2} \right) \]

and

\[ \delta_f \leq \frac{\eta}{24} c^3 \epsilon^{3/2}, \]

where \( c := \min\{c_n, c_n, c_{rn}\} \), the expected function decrease satisfies:

\[ \mathbb{E} \left[ f(x_k + \alpha_k d_k) - f(x_k) \mid \mathcal{F}_{k-1} \right] \leq -\pi_k \hat{c} \epsilon^{3/2} \leq -\hat{c} \varrho \left( c\epsilon^{1/2} \right) \epsilon^{3/2}, \]

where

\[ \hat{c} := \frac{\eta}{12} c^3 \epsilon. \]

**Proof.** We consider in turn the three possible steps that can be taken at iteration \( k \), and obtain a lower bound on the amount of decrease obtained for each of those. To this end, we will make use of the fact that (33) implies

\[ \pi_k \geq \max \left\{ \varrho \left( c_n\epsilon^{1/2} \right), \varrho \left( c_n\epsilon^{1/2} \right), \varrho \left( c_{rn}\epsilon^{1/2} \right) \right\} \]

thanks to the non-increasing property of the function \( \varrho \).

**Case 1:** \( -\lambda_k > \|g_k\|^{1/2} \). By the assumption (32), one has \( -\lambda_k \geq \epsilon^{1/2} \) (in fact, by (32) and \( -\lambda_k > \|g_k\|^{1/2} \), we know that \( -\lambda_k < \epsilon^{1/2} \) cannot hold). Hence, one has

\[ \pi_k \geq \varrho \left( c_n\epsilon^{1/2} \right) \geq \varrho (c_n[-\lambda_k]) \quad \text{and} \quad \delta_f \leq \frac{\eta}{24} c_n^3 \epsilon^{3/2} \leq \frac{\eta}{24} c_n^3 [\epsilon^{-1/2}], \]

thus, by using Lemma 3.1, one gets

\[ \mathbb{E} \left[ f(x_k + \alpha_k d_k) - f(x_k) \mid \mathcal{F}_{k-1} \right] \leq -\pi_k \frac{\eta}{12} c_n^3 [\epsilon^{-1/2}] \]

\[ \leq -\pi_k \frac{\eta}{12} c_n^3 \epsilon^{3/2} \leq -\pi_k \hat{c} \epsilon^{3/2}. \]
If putting the three cases together, we arrive at the desired conclusion. \[\pi_k \geq \varrho \left( c_n \epsilon^{1/2} \right) \geq \varrho \left( c_n \|\tilde{g}_k\|^{1/2} \right)\] and \[\delta_f \leq \frac{\eta}{24} c_n^3 \epsilon^{3/2} \leq \frac{\eta}{24} c_n^3 \|\tilde{g}_k\|^{3/2},\]

and applying Lemma 3.2 yields:
\[
E \left[ f(x_k + \alpha_k d_k) - f(x_k) \mid \mathcal{F}_{k-1} \right] \leq -\pi_k p \frac{\eta}{12} c_n^3 \|\tilde{g}_k\|^{3/2}
\leq -\pi_k p \frac{\eta}{12} c_n^3 \epsilon^{3/2}
\leq -\pi_k \hat{c} \epsilon^{3/2}.
\]

**Case 2:** If \(\lambda_k > \|g_k\|^{1/2}\). By (32), one has \(\|\tilde{g}_k\| = \min\{\|g_k\|, \|g_k\|^{1/2}\} > \epsilon\). Thus,
\[\pi_k \geq \varrho \left( c_n \epsilon^{1/2} \right) \geq \varrho \left( c_n \|\tilde{g}_k\|^{1/2} \right)\]
and \[\delta_f \leq \frac{\eta}{24} c_n^3 \epsilon^{3/2} \leq \frac{\eta}{24} c_n^3 \|\tilde{g}_k\|^{3/2},\]

and applying Lemma 3.2 yields:
\[
E \left[ f(x_k + \alpha_k d_k) - f(x_k) \mid \mathcal{F}_{k-1} \right] \leq -\pi_k p \frac{\eta}{12} c_n^3 \|\tilde{g}_k\|^{3/2}
\leq -\pi_k p \frac{\eta}{12} c_n^3 \epsilon^{3/2}
\leq -\pi_k \hat{c} \epsilon^{3/2}.
\]

**Case 3:** \(|\lambda_k| \leq \|g_k\|^{1/2}\). By the assumption (32), one has \(\|\tilde{g}_k\| = \min\{\|g_k\|, \|g_k\|^{1/2}\} > \epsilon\), which means that \(\min\{\|\tilde{g}_k\| \epsilon^{-1/2}, \epsilon^{1/2}\} \geq \epsilon^{1/2}\). Consequently,
\[
\left\{ \begin{array}{l}
\pi_k \geq \varrho \left( c_n \epsilon^{1/2} \right) \geq \varrho \left( c_n \min\{\|g_k\| \epsilon^{-1/2}, \epsilon^{1/2}\} \right)
\text{and}
\delta_f \leq \frac{\eta}{24} c_n^3 \epsilon^{3/2} \leq \frac{\eta}{24} c_n^3 \min \{\|\tilde{g}_k\| \epsilon^{-3/2}, \epsilon^{3/2}\},
\end{array} \right.
\]
hence we are in the assumptions of Lemma 3.3. Therefore,
\[
E \left[ f(x_k + \alpha_k d_k) - f(x_k) \mid \mathcal{F}_{k-1} \right] \leq -\pi_k p \frac{\eta}{12} c_n^3 \min \{\|\tilde{g}_k\| \epsilon^{-3}, \epsilon^{3}\}
\leq -\pi_k p \frac{\eta}{12} c_n^3 \epsilon^{3/2}
\leq -\pi_k \hat{c} \epsilon^{3/2}.
\]

By putting the three cases together, we arrive at the desired conclusion. ■

In the next section, we will see how the result of Proposition 3.1 can be used to derive a global convergence rate for Algorithm 1.

### 4 Global Convergence Rate and Complexity Analysis

In this section, we provide a global rate of convergence towards an approximate stationary point in expectation for our method, that is, an iterate such that
\[\|\nabla f(x_k)\| \leq \epsilon \quad \text{and} \quad \lambda_{\min}(\nabla^2 f(x_k)) \geq -\epsilon^{1/2}.\] (38)

A point satisfying these conditions will be called an \((\epsilon, \epsilon^{1/2})\)-stationary point. This specific choice of first- and second-order tolerances has been observed to yield optimal complexity bounds for a number of algorithms, in the sense that the dependence on \(\epsilon\) is minimal (see e.g. [9, 29]). The decision between the various choices of directions in Algorithm 1 was also made with these choices in mind.

Since our method only operates with a (subsampling) model of the objective, we are only able to observe if the current iterate is an \((\epsilon, \epsilon^{1/2})\)-model stationary point (for iteration \(k\)), i.e. if
\[
\min\{\|g(x_k; S_k)\|, \|g(x_{k+1}; S_k)\|\} \leq \epsilon \quad \text{and} \quad \lambda_{\min}(H(x_k; S_k)) \geq -\epsilon^{1/2}.\] (39)

Our goal is thus to relate this model stationarity property to (38). For this purpose, we first establish a general result regarding the expected number of iterations required to reach model stationarity. We then study the implications of such a property on the stationarity nature of the iterates with respect to the true objective function, in relation with a possible stopping criterion for Algorithm 1.
4.1 Expected iteration complexity

In addition to the results from the previous section, the proof of our expected complexity bound will rely on two arguments from martingales and stopping time theory. The first one is a martingale convergence result [26, Theorem 1], adapted to our setting in Theorem 4.1.

**Theorem 4.1**

Let \((\Omega, \mathcal{T}, \mathbb{P})\) be a probability space. Let \(\mathcal{F} = \mathcal{T}^k\) be a sequence of sub-sigma algebras of \(\mathcal{T}\) such that \(\mathcal{T}^k \subset \mathcal{T}^{k+1}\).

If \(\alpha^k\) is a positively valued sequence of random variables on \(\mathcal{F}\), and there is a deterministic sequence \(\nu^k \geq 0\) such that,

\[
\mathbb{E}[\alpha^{k+1}|\mathcal{T}^k] + \nu^k \leq \alpha^k
\]

then \(\alpha^k\) converges to a \([0, \infty)\)-valued random variable almost surely and \(\sum_k \nu^k < \infty\).

At each iteration, Proposition 3.1 guarantees a certain expected decrease for the objective function. Theorem 4.1 will be used to show that such a decrease cannot hold indefinitely if the objective is bounded from below.

The second argument comes from stopping time analysis (see, e.g., [28, Theorem 6.4.1]) and is given in Theorem 4.2. The notations have been adapted to our setting.

**Theorem 4.2**

Let \(T\) be a stopping time for the process \(\{Z_k, k \geq 0\}\) and let \(\bar{Z}_k = Z_k\) for \(k \leq T\) and \(\bar{Z}_k = Z_T\) for \(k > T\). If either one of the three properties below hold:

- \(\bar{Z}_k\) is uniformly bounded;
- \(T\) is bounded;
- \(\mathbb{E}[T] < \infty\) and there is an \(R < \infty\) such that \(\mathbb{E}[|Z_{k+1} - Z_k| | Z_0, \ldots, Z_k] < R\);

Then, \(\mathbb{E}[\bar{Z}_k] \to \mathbb{E}[Z_T]\). Moreover, \(\mathbb{E}[Z_T] \geq \mathbb{E}[Z_0]\) (resp. \(\mathbb{E}[Z_T] \leq \mathbb{E}[Z_0]\)) if \(\{Z_k\}\) is a submartingale (resp. a supermartingale).

Theorem 4.2 enables us to exploit the martingale-like property of Definition 3.2, to characterize the index of the first stationary point encountered by the method.

Using the two results along with Proposition 3.1, we bound the expected number of iterations needed by Algorithm 1 to produce an approximate stationary point.

**Theorem 4.3**

Let Assumptions 3.1, 3.2, 3.3 and 3.4 hold, with \(\delta_f\) satisfying (34). Suppose that for every index \(k\), the sample size \(\pi_k\) satisfies (33).

Define \(T_\epsilon\) as the first iteration index \(k\) of Algorithm 1 for which

\[
\min\{\|g_k\|, \|g_k^+\|\} < \epsilon \quad \text{and} \quad \lambda_k > -\epsilon^{1/2}.
\]

Then, \(T_\epsilon < \infty\) almost surely, and

\[
\mathbb{E}[T_\epsilon] \leq \begin{cases} 
(\frac{f(x_0) - f_{\text{low}}}{\epsilon}) \epsilon^{-3/2} + 1 & \text{if } \pi_k = 1 \ \forall k; \\
(\frac{f(x_0) - f_{\text{low}}}{\epsilon}) \hat{c}(\epsilon \epsilon^{1/2})^{-1} \epsilon^{-3/2} + 1 & \text{otherwise},
\end{cases}
\]

(40)

where \(\hat{c}\) is given by (36).
Proof. Since $x_k, S_k \in \mathcal{F}_k^2$, we have $\{T_\epsilon = k\} \in \mathcal{F}_k$ for all $k$, thus $T_\epsilon$ is indeed a stopping time.

Suppose first that $\{T_\epsilon = \infty\}$ has a nonzero probability of occurrence. Under this event, then for every iteration index $k$, we are in the assumptions of Proposition 3.1. For notational convenience, we define

$$c_\epsilon = \begin{cases} \hat{c} \epsilon^{3/2} & \text{if } \pi_k = 1 \ \forall k; \\ \hat{c} \rho \epsilon^{1/2} \epsilon^{3/2} & \text{otherwise.} \end{cases}$$

Then, at every iteration $k < T_\epsilon$, we have $E[f(x_{k+1}) - f(x_k)|\mathcal{F}_{k-1}] \leq -c_\epsilon$ thanks to Proposition 3.1. This leads to:

$$\begin{align*}
E[f(x_{k+1}) - f(x_k)|\mathcal{F}_{k-1}] & \leq -c_\epsilon \\
E[f(x_{k+1})|\mathcal{F}_{k-1}] + c_\epsilon & \leq E[f(x_k)|\mathcal{F}_{k-1}] \\
E[f(x_{k+1})|\mathcal{F}_{k-1}] + c_\epsilon & \leq f(x_k),
\end{align*}$$

where the last relation comes from the fact that $x_k \in \mathcal{F}_{k-1}$. Subtracting $f_{\text{low}}$ on both sides yields:

$$E[f(x_{k+1}) - f_{\text{low}}|\mathcal{F}_{k-1}] + c_\epsilon \leq f(x_k) - f_{\text{low}},$$

As a result, we can apply Theorem 4.1 with $\alpha^k = f(x_k) - f_{\text{low}} \geq 0$, $\tau^k = \mathcal{F}_{k-1}$ and $\nu^k = c_\epsilon > 0$: we thus obtain that $\sum_{k=0}^{\infty} c_\epsilon < \infty$, which is obviously false. Thus, $T_\epsilon$ must be finite almost surely.

Consider now the sequence of random variables given by,

$$R_k = f(x_{\text{min}(k,T_\epsilon)}) + \max(\text{min}(k,T_\epsilon) - 1, 0) c_\epsilon.$$

Proposition 3.1 ensures that for any $k < T_\epsilon$, one has

$$E[R_{k+1}|\mathcal{F}_k] = E[f(x_{k+1})|\mathcal{F}_k] + k c_\epsilon$$

and for $k \geq T_\epsilon$, trivially $R_{k+1} = R_k$, and thus $R_k$ is a supermartingale. Moreover,

$$E[|R_{k+1} - R_k| |\mathcal{F}_{k-1}] = E[|R_{k+1} - R_k| |\mathcal{F}_{0}, \ldots, \mathcal{F}_k] \leq c_\epsilon < \infty.$$
Lemma 4.1 Let Assumptions 3.1 and 3.2 hold. Consider a realization of the method that reaches an iterate $x_k$ such that

$$\|g_k\| \leq \epsilon \quad \text{and} \quad \lambda_k \geq -\epsilon^{1/2},$$

and that the model $m_k$ is $(\delta_f, \delta_g, \delta_h)$-accurate with

$$\delta_g \leq c_g \epsilon, \quad \delta_h \leq c_h \epsilon^{1/2}$$

(43)

where $c_g$ and $c_h$ are positive, deterministic constants independent of $k$. Then, $x_k$ is a $((1 + c_g)\epsilon, (1 + c_h)\epsilon^{1/2})$-stationary point.

Proof. Let $x_k$ be an iterate such that

$$\|g_k\| \leq \epsilon \quad \text{and} \quad \lambda_k \geq -\epsilon^{1/2}.$$ 

Consider a unit eigenvector $v$ for $\nabla^2 f(x_k)$ associated with $\lambda_{\min}(\nabla^2 f(x_k))$, one has

$$\lambda_k - \lambda_{\min}(\nabla^2 f(x_k)) \leq v^T H_k v - v^T \nabla^2 f(x_k) v \leq \|H_k - \nabla^2 f(x_k)\| \|v\|^2 \leq \delta_H.$$ 

Hence, by using (43), one gets

$$\|\nabla f(x_k)\| \leq \|\nabla f(x_k) - g_k\| + \|g_k\| \leq \delta_g + \epsilon \leq (c_g + 1)\epsilon,$$

and

$$\lambda_{\min}(\nabla^2 f(x_k)) = (\lambda_{\min}(\nabla^2 f(x_k)) - \lambda_k) + \lambda_k \geq -\delta_H - \epsilon^{1/2} \geq -(c_h + 1)\epsilon^{1/2},$$

meaning that $x_k$ is also $((1 + c_g)\epsilon, (1 + c_h)\epsilon^{1/2})$-stationary point. 

Combining Theorem 4.3 and Lemma 4.1, we thus have that after $O(\varrho(\epsilon^{1/2})\epsilon^{-3/2})$ iterations (in the general case), if a point is model stationary and the model happens to be accurate, then we can conclude that the point is also stationary for the true function.

The result of Lemma 4.1 is only valid when the model is accurate. In the context of Algorithm 1, we assume that our models are probabilistically accurate, and thus we only have probabilistic guarantees that model stationary iterates are stationary for the true objective. One possible way of strengthening this result consists in requiring model stationarity to be satisfied for a certain number of successive iterations. This is the sense of the following proposition.

Proposition 4.1 Under the assumptions of Theorem 4.3, suppose that Algorithm 1 reaches an iteration index $k + J$ such that for every $j \in \{k, k + 1, \ldots, k + J\}$,

$$\|g_j\| \leq \epsilon, \quad \|g_j^+\| \leq \epsilon \quad \text{and} \quad \lambda_j \geq -\epsilon^{1/2}.$$ 

Suppose further that $\delta_g$ and $\delta_h$ satisfy (43), and that the sample sizes are selected independently of the current iterate. Then, with at probability at least $1 - (1 - p)^{J+1}$, where $p$ is the lower bound on $p_k$ given by Assumption 3.4, one of the iterates $\{x_k, x_{k+1}, \ldots, x_{k+J}\}$ is $((1 + c_g)\epsilon, (1 + c_h)\epsilon^{1/2})$-stationary.
**Proof.** In this proof, we will use the notation $\mathbb{P}_k(\ldots) = \mathbb{P}(\cdot|\mathcal{F}_{k-1})$. Recall the event $I_j$ from Definition 3.2. We also consider the random events $E = \{\text{One of the iterates } x_k, x_{k+1}, \ldots, x_{k+J}\}$ is $((1 + c_k)\epsilon, (1 + c_h)\epsilon^{1/2})$-stationary, and

\[\forall j = 0, \ldots, J, \quad E_j = \{\text{The iterate } x_{k+j}\text{ is } (\epsilon, \epsilon^{1/2})\text{-model stationary}\}.\]

For every $j = 0, \ldots, J$, we have $E_j \in \mathcal{F}_{k+j}$ and $I_{k+j} \in \mathcal{F}_{k+j}$. Moreover, the event $E_j$ and $I_{k+j}$ are conditionally independent, i.e. for every $j = 0, \ldots, J$,

\[\mathbb{P}_k(E_j \cap I_{k+j}|\mathcal{F}_{k+j-1}) = \mathbb{P}_k(E_j|\mathcal{F}_{k+j-1}) \mathbb{P}_k(I_{k+j}|\mathcal{F}_{k+j-1}).\]  

This conditional independence holds because $x_{k+j} \in \mathcal{F}_{k+j-1}$, and the model $m_{k+j}$ is constructed independently of $x_{k+j}$ by assumption.

The statement of the theorem corresponds to

\[\mathbb{P}_k(E|E_0, \ldots, E_J) \geq 1 - (1 - p)^{J+1},\]

which is what we want to prove. By Lemma 4.1,

\[\mathbb{P}_k(E|E_0, \ldots, E_J) \geq \mathbb{P}_k\left(\bigcup_{0 \leq j \leq J} I_{k+j} \bigg| E_0, \ldots, E_J\right) = 1 - \mathbb{P}_k\left(\bigcap_{0 \leq j \leq J} \bar{I}_{k+j} \bigg| E_0, \ldots, E_J\right),\]

and it thus suffices to prove that

\[\mathbb{P}_k\left(\bigcap_{0 \leq j \leq J} \bar{I}_{k+j} \bigg| E_0, \ldots, E_J\right) \leq (1 - p)^{J+1}\]  

(45)

to obtain the desired result.

We will use a property coming from the definition of the probabilistically accuracy. For every $j = 0, \ldots, J$, we have

\[\mathbb{P}_k(I_{k+j}|A) \geq p,\]  

(46)

for any set of events $A$ belonging to the $\sigma$-algebra $\mathcal{F}_{k+j-1}$ [16, Chapter 5]. In particular, for any $j \geq 1$, $\mathbb{P}_k(I_{k+j}|I_k, \ldots, I_{k+j-1}, E_0, \ldots, E_J) \geq p$.

Returning to our target probability, we have:

\[
\begin{align*}
\mathbb{P}_k\left(\bigcap_{0 \leq j \leq J} \bar{I}_{k+j} \bigg| E_0, \ldots, E_J\right) &\leq \mathbb{P}_k\left(I_J \cap E_0, \ldots, E_J \cap I_0, \ldots, I_{k+j-1}\right) \times \mathbb{P}_k\left(\cap_{0 \leq j \leq J} \bar{I}_{k+j} \bigg| E_0, \ldots, E_J\right) \\
&= \frac{\mathbb{P}_k\left(I_J \cap E_0, \ldots, E_J \cap I_0, \ldots, I_{k+j-1}\right) \mathbb{P}_k\left(\cap_{0 \leq j \leq J} \bar{I}_{k+j} \bigg| E_0, \ldots, E_J\right)}{\mathbb{P}_k\left(I_J \cap E_0, \ldots, E_J \bigg| E_0, \ldots, E_J\right)} \\
&= \frac{\mathbb{P}_k\left(I_J \cap E_0, \ldots, E_J \cap I_0, \ldots, I_{k+j-1}\right) \mathbb{P}_k\left(\cap_{0 \leq j \leq J} \bar{I}_{k+j} \bigg| E_0, \ldots, E_J\right)}{\mathbb{P}_k\left(I_J \cap E_0, \ldots, E_J \bigg| E_0, \ldots, E_J\right)} \\
&= \frac{\mathbb{P}_k\left(I_J \cap E_0, \ldots, E_J \cap I_0, \ldots, I_{k+j-1}\right) \mathbb{P}_k\left(\cap_{0 \leq j \leq J} \bar{I}_{k+j} \bigg| E_0, \ldots, E_J\right)}{\mathbb{P}_k\left(I_J \cap E_0, \ldots, E_J \bigg| E_0, \ldots, E_J\right)} \\
&\leq \mathbb{P}_k\left(I_J \cap E_0, \ldots, E_J \cap I_0, \ldots, I_{k+j-1}\right) \times \mathbb{P}_k\left(\cap_{0 \leq j \leq J} \bar{I}_{k+j} \bigg| E_0, \ldots, E_J\right).
\end{align*}
\]
where the last equality comes from (44), and the final inequality uses the fact that the events \(E_0, \ldots, E_{J-1}\) and \(I_k, \ldots, I_{k+J-1}\) are pairwise independent, thus

\[
P_k \left( E_{J} | E_0, \ldots, E_{J-1}, I_k, \ldots, I_{k+J-1} \right) = P_k \left( E_J | E_0, \ldots, E_{J-1} \right).
\]

Using (46), we then have that

\[
P_k \left( \bar{I}_J | E_0, \ldots, E_{J-1}, I_k, \ldots, I_{k+J-1} \right) = 1 - P_k \left( I_J | E_0, \ldots, E_{J-1}, I_k, \ldots, I_{k+J-1} \right) \leq 1 - p.
\]

Thus,

\[
P_k \left( \bigcap_{0 \leq j \leq J} \bar{I}_{k+j} \bigg| E_0, \ldots, E_J \right) \leq (1 - p) P_k \left( \bigcap_{0 \leq j \leq J-1} \bar{I}_{k+j} \bigg| E_0, \ldots, E_{J-1} \right).
\]

By a recursive argument on the right-hand side of (47), we thus arrive at (45), which yields the desired conclusion.

The result of Proposition 4.1 is only of interest if we are guaranteed that such a sequence of model stationary iterates can occur in a bounded number of iterations. This property can be ensured by rejecting a step if it is deemed that the new iterate is not promising in terms of decrease.

**Assumption 4.1** In Algorithm 1, Step 7 is replaced by:

7'. If \(\|\tilde{g}_k\| < \epsilon\) and \(\lambda_k > -\epsilon^{1/2}\), set \(x_{k+1} = x_k\), otherwise set \(x_{k+1} = x_k + \alpha_k d_k\). Set \(k = k + 1\).

Moreover, the sample size is selected independently of the current iterate.

Under this assumption, we can assess stationarity at a given iterate based on a series of samples. Theorem 4.4 provides the result, that extends that of Theorem 4.3.

**Theorem 4.4** Let Assumptions 3.1, 3.2, 3.3, 3.4 and 4.1 hold, with \(\delta_f\) satisfying (34). Suppose that for every index \(k\), the sample size \(\pi_k\) satisfies (33).

For a given \(J \in \mathbb{N}\), define \(T_{\epsilon,J}\) as the first iteration index of Algorithm 1 for which

\[
\min\{\|g_k\|, \|g_k^+\|\} < \epsilon \quad \text{and} \quad \lambda_k > -\epsilon^{1/2}, \quad \forall k \in \{T_{\epsilon,J}, T_{\epsilon,J} + 1, \ldots, T_{\epsilon,J} + J\}.
\]

Then, \(T_{\epsilon,J} < \infty\) almost surely, and

\[
\mathbb{E}[T_{\epsilon,J}] \leq \begin{cases} \frac{(f(x_0) - f_{\text{low}})}{\epsilon} \epsilon^{-3/2} + 1 & \text{if } \pi_k = 1 \forall k; \\ (J + 1) \left[ \frac{(f(x_0) - f_{\text{low}})}{\epsilon} q(\epsilon_1^{1/2}) \right]^{-1} \epsilon^{-3/2} + 1 & \text{otherwise,} \end{cases}
\]

**Proof.** As for Theorem 4.3, \(T_{\epsilon,J}\) clearly is a stopping time. Moreover, if \(\pi_k = 1\) for all \(k\), then \(T_{\epsilon,J} = T_\epsilon\) for every \(J\), where \(T_\epsilon\) is the stopping time defined in Theorem 4.3, and therefore the result holds. In what follows, we focus on the remaining case: the goal of the proof is to exhibit a subsequence of iterates on which the reasoning of the proof of Theorem 4.3 can be applied.

Suppose first that \(T_{\epsilon,J} = \infty\): then for every iteration index \(k\), there exists an index in \(\{k, \ldots, k + J\}\) such that the corresponding iterate is not model stationary. Let \(j(k)\) be the
smallest index to satisfy this property: we have \( k \leq j(k) \) for every \( k \). Moreover, for any \( k \) we have \( x_{j(k)+1} = x_{j(k)+2} = \cdots = x_{j(k+1)} \), thus we can consider the sequence \( \{x_{j(k)}\}_k \). For any \( k \), at the \( j(k) \)-th iteration, we are in the assumptions of Proposition 3.1, hence, defining \( c_\epsilon \) as in the proof of Theorem 4.3, we have:

\[
\begin{align*}
\mathbb{E} \left[ f(x_{j(k)+1}) - f(x_{j(k)}) \big| \mathcal{F}_{j(k)-1} \right] &\leq -c_\epsilon \\
\mathbb{E} \left[ f(x_{j(k)+1})\mathcal{F}_{j(k)-1} + c_\epsilon \right] &\leq \mathbb{E} \left[ f(x_{j(k)}) \big| \mathcal{F}_{j(k)-1} \right] \\
\mathbb{E} \left[ f(x_{j(k)+1})\mathcal{F}_{j(k)-1} + c_\epsilon \right] &\leq f(x_{j(k)}),
\end{align*}
\]

where the second-to-last relation comes from the fact that \( x_{j(k)} \in \mathcal{F}_{j(k)-1} \). By subtracting \( f_{\text{low}} \) on both sides of the equations and using \( x_{j(k)+1} = x_{j(k+1)} \), we can rewrite the above relation as

\[
\mathbb{E} \left[ f(x_{j(k)+1}) - f_{\text{low}} \big| \mathcal{F}_{j(k)-1} \right] + c_\epsilon \leq f(x_{j(k)}) - f_{\text{low}}. \tag{49}
\]

We can thus apply Theorem 4.1 with \( \alpha^k = f(x_{j(k)}) - f_{\text{low}} \geq 0 \) and for every \( k \), \( T^k = \mathcal{F}_{j(k)-1} \) and \( v^k = c_\epsilon \). We then obtain that \( \sum_{k=0}^{\infty} c_\epsilon < \infty \), which is obviously false, from which we conclude that \( T_{\epsilon,J} \) is finite almost surely.

Using the sequence \( \{j(k)\}_k \), we now define the (sub)sequence of iterations that are not model stationary,

\[
\{k_0, k_1, \ldots\} = \{k \mid k = j(k) \text{ and } k < T_{\epsilon,J}\}.
\]

and we denote by \( k_{J-1,\epsilon} \) the maximum element of that ensemble. For any \( l \geq J_\epsilon \), we set \( k_l = T_{\epsilon,J} \).

We can now define for every \( l \in \mathbb{N} \):

\[
R_l = f \left( x_{\min(j(k_l),T_{\epsilon,J})} \right) + \max\{\min(l, J_\epsilon) - 1, 0\} c_\epsilon.
\]

By (49), we then have for any \( l \) such that \( k_l < T_{\epsilon,J} \):

\[
\mathbb{E}[R_{l+1}\big|\mathcal{F}_{j(k_l)-1}] = \mathbb{E}[f(x_{j(k_{l+1})})\big|\mathcal{F}_{j(k_l)-1}] + l c_\epsilon \leq f(x_{j(k_l)}) - c_\epsilon + l c_\epsilon = R_l
\]

and for \( l \geq T_{\epsilon,J} \), trivially \( R_{l+1} = R_l \), and thus \( R_l \) is a supermartingale.

Since \( T_{\epsilon,J} < \infty \) almost surely, by Theorem 4.2, it holds that \( \mathbb{E}[R_{J_\epsilon}] \leq \mathbb{E}[R_0] \) which implies that,

\[
f_{\text{low}} + (\mathbb{E}[J_\epsilon] - 1)c^{3/2} \leq \mathbb{E}[R_{J_\epsilon}] \leq \mathbb{E}[R_0] = f(x_0)
\]

and thus,

\[
\mathbb{E}[J_\epsilon] \leq \frac{(f(x_0) - f_{\text{low}})}{c^{3/2}} + 1.
\]

We then conclude by noticing that \( T_{\epsilon,J} \leq (J + 1) \times J_\epsilon. \)

With the result of Theorem 4.4, we are guaranteed that there will exist consecutive iterations satisfying model stationarity, and thus checking for those is a valid stopping criterion in practice. If an estimate of the probability \( p \) is known (see the next section), one can even choose \( J \) to guarantee that the probability of computing a stationary iterate is sufficiently high.
Evaluation complexity: As a final note to this section, we observe that the number of evaluations of \( f_i \) and their derivatives is bounded in expectation, thanks to the result of Theorem 4.4. Note that we must account for the additional objective evaluations induced by the line-search process (see [29, Theorem 8] for details).

**Corollary 4.1** Under the assumptions of Theorem 4.4, assuming that the sample size condition (33) is satisfied with \( \pi_k \in \{ \rho(\epsilon), 1 \} \) for every \( k \), the expected number of evaluations of \( \nabla f_i \) and \( \nabla^2 f_i \) are respectively bounded above by

\[
\begin{cases}
  (f(x_0) - f_{\text{low}}) \epsilon^{-3/2} + 1 & \text{if } \pi_k = 1 \ \forall k; \\
  (J + 1) \left( \frac{f(x_0) - f_{\text{low}}}{\epsilon} \right) \rho(\epsilon^{1/2})^{-1} \epsilon^{-3/2} + 1 & \text{otherwise},
\end{cases}
\]

while the expected number of function evaluations is bounded above by

\[
(1 + \max\{j_{nc}, j_n, j_{rn}\}) \times \begin{cases}
  (f(x_0) - f_{\text{low}}) \epsilon^{-3/2} + 1 & \text{if } \pi_k = 1 \ \forall k; \\
  (J + 1) \left( \frac{f(x_0) - f_{\text{low}}}{\epsilon} \right) \rho(\epsilon^{1/2})^{-1} \epsilon^{-3/2} + 1 & \text{otherwise}.
\end{cases}
\]

The bounds (50) and (51) match their deterministic counterparts (see [29]) in the worst case.

### 4.2 Illustration of sample and evaluation complexity for uniform sampling

The two main requirements made in the analysis of the previous section are related to the function value accuracy \( \delta_f \) and the sample size \( \pi_k \). Specifically, for a given tolerance \( \epsilon \), we require

1. \( \delta_f \leq \frac{\eta}{24} c^3 \epsilon^{3/2} \) (equation (34));
2. \( \pi_k \geq \rho(\epsilon^{1/2}) = \frac{U_g + L \epsilon^{1/2} + \frac{U_c}{2} \epsilon \gamma^2}{U_g + L \epsilon^{1/2} + \frac{U_c}{2} \epsilon \gamma^2} \) (equation (33)).

In this section, we provide estimates of the minimum number of samples necessary to achieve those two conditions in the case of a uniform sampling strategy. To facilitate the exposure, we discard the case \( p = 1 \) and focus on \( p \in (0, 1) \).

For the rest of the section, we thus suppose that the set \( S_k \) is formed of \( n \tilde{\pi} \) indexes chosen uniformly at random with replacement. where \( \tilde{\pi} \) is independent of \( k \). That is, for every \( i \in S_k \) and every \( j = 1, \ldots, N \), we have \( \mathbb{P}(i = j) = \frac{1}{N} \). This case has been well studied in the case of subsampled Hessian [31] and subsampled gradient [27]. The lemmas below summarize the results.

**Lemma 4.2** Under Assumptions 3.2 and 3.3, consider an iterate \( x_k \) of Algorithm 1. For any \( \rho \in (0, 1) \), if the sample set \( S_k \) is chosen to be of size

\[
\tilde{\pi} \geq \frac{1}{N} \frac{16L^2}{\delta_H} \ln \left( \frac{2N}{1-p} \right),
\]

then

\[
\mathbb{P} \left( \| H(x_k; S_k) - \nabla^2 f(x_k) \| \leq \delta_H | \mathcal{F}_{k-1} \right) \geq p.
\]
Proof. See [31, Lemma 4]; note that here we are using $L_i$ (Lipschitz constant of $\nabla f_i$) as a bound on $\|\nabla^2 f_i(x_k)\|$, and that we are providing a bound on the sampling fraction $\bar{\pi} = \frac{|S_k|}{N}$. ■

By the same reasoning as for Lemma 4.2, but in one dimension, we can readily provide a sample size bound for obtaining accurate function values. To this end, we define

$$f_{up} \geq \max_k \max_{i=1,\ldots,N} f_i(x_k).$$

Note that there exists such a bound when Assumption 3.3 is satisfied, and specific structure of the problem could allow for it to available (in the case of a loss function, for instance, one can often choose $f_{up} = 1$).

**Lemma 4.3** Under Assumptions 3.2 and 3.3, consider an iterate $x_k$ of Algorithm 1. For any $p \in (0,1)$, if the sample set $S_k$ is chosen to be of size

$$\bar{\pi} \geq \frac{1}{N} \frac{16 f_{up}^2}{\delta_f} \ln \left(\frac{2}{1-p}\right),$$

then

$$\mathbb{P}\left( |m(x_k; S_k) - f(x_k)| \leq \delta_f |F_{k-1}| \right) \geq p.$$

Proof. The proof follows that of [31, Lemma 4.1] by considering $m(x_k; S_k)$ and $f(x_k)$ as one-dimensional matrices. ■

**Lemma 4.4** Under Assumptions 3.2 and 3.3, consider an iterate $x_k$ of Algorithm 1. For any $\varrho \in (0,1)$, if the sample set $S_k$ is chosen to be of size

$$\bar{\pi} \geq \frac{1}{N} \frac{U_g^2}{\delta_g} \left[1 + \sqrt{8 \ln \left(\frac{1}{1-p}\right)}\right]^2,$$

then

$$\mathbb{P}\left( \|g(x_k; S_k) - \nabla f(x_k)\| \leq \delta_g |F_{k-1}| \right) \geq p.$$

Proof. See [27, Lemma 2]. ■

By combing those three lemmas, we obtain the following sample size condition.

**Theorem 4.5** Let Assumptions 3.1, 3.2 and 3.3 hold. Suppose that the sample fractions $\pi_k$ of Algorithm 1 are chosen to satisfy $\pi_k \geq \pi(\epsilon)$ for every $k$, where

$$\pi(\epsilon) := \frac{1}{N} \max \left\{ N \rho(c \epsilon^{1/2}), \frac{344 f_{up}^2}{\eta c^3 \epsilon^{3/2}} \ln \left(\frac{2}{1-p}\right), \frac{U_g^2}{\delta_g^2} \left[1 + \sqrt{8 \ln \left(\frac{1}{1-p}\right)}\right]^2, \frac{16 L^2}{c_h \epsilon^{1/2}} \ln \left(\frac{2N}{1-p}\right) \right\}. \quad (56)$$

Then, the model sequence is $p$-probabilistically $(\delta_f, \delta_g, \delta_h)$-accurate with $\delta_f = \frac{n}{23} c^3 \epsilon^{3/2}$, $\delta_g = c_g \epsilon$ and $\delta_h = c_h \epsilon^{1/2}$. Moreover, the results from Section 4.1 hold.

We observe that explicit computation of these bounds would require estimating $L, L_H$ and $U_g$. If orders of magnitude for the aforementioned quantities are available, they can also be used for choosing the sample size.
4.3 Comparison with other sample complexities

By looking at several existing sample complexity results in the literature, we can position our method within the existing landscape of results, and get insight about the cost of second-order requirements, as well as that of using inexact function values.

When applied to nonconvex problems, a standard stochastic gradient approach with fixed step size has a complexity in \( O(\epsilon^{-4}) \) (both in terms of iterations and gradient evaluations) for reaching approximate first-order optimality [17]. Modified SGD methods that take curvature information can significantly improve over that bound, one recent example being the Natasha 2 method that requires \( O(\epsilon^{-3.25}) \) iterations/gradient evaluations for reaching \( \|\nabla f(x_k)\| \leq \epsilon \) and \( \nabla^2 f(x_k) \succeq -\epsilon^{1/4} I \) [2]. Note that those guarantees are on the true derivatives, and not their expected value/estimates. These orders hold in high probability, and thus are not informative in the event of a poor approximation at one step of the procedure. Our results are able to cover such a situation. Note that we can also turn our results to high-probability rates, following for instance an argument similar to [18].

It is also interesting to compare our complexity orders with those obtained by first-order methods in stochastic optimization. Stochastic trust-region methods [13, 21] typically require \( O(\Delta_k^{-4}) \) samples per iteration, where \( \Delta_k \) is the trust-region radius and serves as an approximation of the norm of the gradient. Similarly, the line-search algorithm of Paquette and Scheinberg [25] guarantees sufficient accuracy in the function values if the sample size is of order \( O(\alpha_k^{-2}\|g_k\|^{-2}) \) (we use our notations for consistency), which for our method roughly corresponds to \( O((\alpha_k\|d_k\|)^{-2}) \). Our sample complexity is of order \( O((\alpha_k\|d_k\|)^{-3}) \) but possesses second-order convergence rates. One could thus conjecture that endowing the algorithm of [25] with second-order guarantees in expectation would increase the sample complexity from \( O((\alpha_k\|d_k\|)^{-2}) \) to \( O((\alpha_k\|d_k\|)^{-3}) \).

Finally, we discuss sample bounds for Newton-based methods in a subsampling context. In [31], it was shown that the desired complexity rate of \( O(\epsilon^{-3/2}) \) is achieved with probability \( 1-p \), if the proportion of samples taken from the sum of samples satisfies,

\[ |S| \geq \frac{16U^2_H}{\epsilon^2} \ln \left( \frac{2N}{p} \right) \]

and in [23] we have a similar result where \( S \) must satisfy,

\[ |S| \geq \frac{16L^2}{\epsilon^2} \ln \left( \frac{2N}{p} \right) . \]

In both cases, the desired samples are proportional to a constant measuring the size of the problem data and inversely proportional to the desired tolerance squared, as in our case. In [33] high probability results were derived with the accuracy of the function gradient and Hessian estimates \( \delta_g \) and \( \delta_H \) being bounded by \( \epsilon \). In part because of the accuracy requirements on the gradient, the resulting sampling bounds are \( O(\epsilon^{-2}) \). In our setting, we require the function accuracy to be of order of order \( \epsilon^{3/2} \), where \( \epsilon \) is the gradient tolerance. The dependencies yet on \( \epsilon \) suggested by Lemma 4.1 and 4.5 thus appear similar to those present in the literature [31, 33]. As mentioned above, they also bear a close connection with the norm of the steps; a similar property was used to define probabilistic models in trust-region methods [3].
5 Numerical Illustration

In this section, as a proof of concept, we will evaluate the performance of our proposed algorithm in comparison with classical gradient-based methods. To this end, we consider a binary classification problem where one tries to minimize a non-linear least squares loss function. More precisely, given a training set \( \{ z_i, y_i \}_{i=1}^{N} \) where \( z_i \in \mathbb{R}^n \) and \( y_i \in \{0, 1\} \), we consider the following empirical risk minimization problem,

\[
\min_{x \in \mathbb{R}^n} \frac{1}{N} \sum_{i=1}^{N} (y_i - \Phi(z_i^T x))^2,
\]

(57)

where \( \Phi \) is the sigmoid function, i.e., \( \Phi(w) = \frac{1}{1+\exp(-w)} \) for all \( w \in \mathbb{R} \). Our training data comes from the IJCNN1 dataset, itself obtained from the LIBSVM library [12]: for this dataset, we have \( N = 49990 \) and \( n = 22 \).

The basic parameters in Algorithm 1 are set to \( \epsilon = 10^{-5}, \eta = 10^{-2}, \) and \( \theta = 0.9 \). Our tests include three variants of Algorithm 1 identified as follows:

- **ALAS-ALGO (full)**: Algorithm 1 using exact function, gradient and Hessian (i.e., using the entire dataset, \( S = \{1, \ldots, N\} \)).
- **ALAS-ALGO (5%)**: Algorithm 1 with a uniform subsampling to generate \( S \) and using 5% of the entire dataset.
- **ALAS-ALGO (1%)**: Algorithm 1 with a uniform subsampling to generate \( S \) and using 1% of the entire dataset.

Similarly, our experiments include three variants of a basic implementation of the stochastic gradient descent method, with the same sampling strategies as the ALAS-ALGO schemes. Those variants are called SGD-ALGO (full) (equivalent to deterministic gradient descent), SGD-ALGO (5%) and SGD-ALGO (1%), and all three variants use a step size of 0.1. As a stopping criterion for all the tested solvers, we require \( (\epsilon, \epsilon^{1/2}) \)-model stationarity with \( \epsilon = 10^{-5} \). When subsampling is used, \( (\epsilon, \epsilon^{1/2}) \)-model stationarity must be satisfied for \( J \) successive iterations, where we chose \( J \) to be 1 epoch (1 epoch of a solver that uses \( s \)% of the dataset is equivalent to running \( \frac{100}{s} \) iterations of this method). This choice was made after testing a number of values, and we believe that it serves our illustrative purpose by exploiting the connection between model stationarity and true objective stationarity studied in Section 4.1.

For all tested solvers, we impose a maximum number of 1600 epochs; in our numerical tests, this maximum number of epochs ensured that at least ALAS-ALGO (full) reached the \( (\epsilon, \epsilon^{1/2}) \)-stationarity (note that in this case, as the full dataset is used, 1 epoch represents one iteration of the algorithm). To account for the randomness in the subsampling process, we performed multiple runs started from different random points. Our runs all yielded similar results, therefore we describe our findings based upon results from a single representative run.

The obtained results are depicted in Figures 1 and 2. The true function value and exact norm gradients are plotted in Figure 1, while Figure 2 shows the exact function values (respectively, exact gradient norm) and the model estimates (respectively, the sampled gradient norm) for ALAS-ALGO using 1% and 5% of the dataset. Overall, several patterns are fairly consistent. First, ALAS-ALGO takes much fewer iterations than all the variants of SGD-ALGO to decrease the objective value and gradient norm, showing the effect of using second-order information.
Admittedly the iteration cost of ALAS-ALGO is higher than SGD, yet the sampling procedure is performed with the same batch size for both: from that metric, ALAS-ALGO yields a better error for the same order of sampling, and requires less passes through the data. We note that both kinds of subsampling methods start plateauing after an initial, fast convergence phase. Our second observation is that for our subsampled methods, convergence is very fast in the beginning of the run in expectation: the methods then enter a regime in which the noise induced by the subsampling process slows down the convergence, as is also the case for the SGD methods. We observe however that the good initial behavior of ALAS-ALGO allows the algorithm to reach better function values for the same number of epochs.

Figure 1: Obtained results on IJCNN1 for binary classification. Logarithmic scales are used for the x-axis and y-axis. The curve markers are placed every $10^2$ epochs for Figures (1(a)) and (1(b)), and every $10^3$ iterations for Figures (1(c)) and (1(d)).
6 Conclusion

In this paper, we presented a line-search method for stochastic optimization, wherein the Hessian, gradient, and function values must be estimated through subsampling and cannot be obtained exactly. Using probabilistically accurate models, we derived a complexity result on the expected number of iterations until an approximate measure of stationary is reached for the current model. This result in expectation is complementary to those holding with high probability, i.e., if an accurate sample is taken at every iteration. In our setting, we are able to obtain convergence in expectation at a rate which is commensurate with the state of the art, regardless of the presence of outliers in sample estimates resulting in poor steps. We also proposed a practical strategy to assess whether the current iterate is close to a sample point for the original objective, that does not require the computation of the full function. Our preliminary numerical results showed the potential of the proposed approach on a standard dataset.
We believe the results of the paper complement the existing literature in a contributive way, and will encourage further study into the design of algorithms appropriate for large scale optimization that are robust with respective to poor sample approximations. The primarily theoretical contributions of this paper will be informative in regards to the design and analysis of stochastic algorithms. In particular, our approach could be helpful in generalizing other line-search techniques to the context of subsampled function values.

To the best of the authors’ knowledge, currently the closest implementation of the procedure described in this paper is given in [20], using proprietary data and thus limited experiments. We are currently working on an extensive numerical study, based on exploiting the practical features of [20] (e.g., inexact matrix operations), on a wider variety of problems implementing training of complex deep neural net architectures. We believe that this ongoing work will further advance the state of the art in the study of stochastic algorithms for finite sum optimization.
